In lithographic or planographic printing the duplicate plates formerly were made by the old hand-transfer method. The operation of transferring the design from the original plate many times over to the press plate did not permit of fidelity and uniformity, because of the method involved, the materials needed, and the widely varying elements in the human factor.

Experience teaches that to be successful in color printing the register must be kept within a 0.003-in. limit of accuracy. In practice the press plate or form bears a multitude of definite images that may or may not vary in size and subject matter and that may be arranged in any number of relative positions.

Each one of the several necessary press plates or forms contains only the portions of the images that are to receive one color, such as yellow or red or blue; and the completed product, in order to receive all of the colors, is printed from a number of composed press plates, each one for a different color.

## Close Register Required in Each Detail

Satisfactory mass production of color work needs commercially perfect registration not only in each of the several color plates composing the completed image, but also in the spacing between the multiplicity of the identical images on each of these forms; and this precise register must be maintained in the relative positions of the various portions of the images on all of the color forms.

Another factor necessary to success is the fidelity of the printed edition to the proof from the original plates.

The amount of each color applied at each impression must be properly controlled, because the color inks are not applied in solid areas, but by the stipples or ink conveyors of the half-tone plates as very small, individual dots. In practice the number of these dots is constant and definite, but the sizes thereof vary in accordance with the amount of color required on different parts of the finished product.

Precise registration for the size and location of these dots or ink conveyors is needed on all of the component color press plates if fidelity of color effect is to be maintained between the printed edition and the original proof.

It is apparent that in stereotype, electrotype, and hand-transfer duplicating methods the final press-plate image for a given color is altered or removed to some degree from the original image by each intermediate step in the duplicating method used.

Each step that changes the size, shape, character, or location of the ink-conveying dots through mis-register alters the fidelity of the color value accordingly.

As said, the advertiser who buys color printing is seeking faithful reproduction of his color "copy."

In mass production of press plates to produce satisfactory color editions, the register is the outstanding factor to successful results. Precise register in the size and position of the ink-conveying dots, as well as precise register in the relative location and position of the images composing each form for the component colors, is essential to successful color editions.

## Mechanical Imposition

Photo composing or photo-mechanical imposition is a comparatively new art or a new branch of the art of printing. It is the art of making printing plates wherein original designs are photographed directly on the press plate from which the finished edition is printed.

Photo composing or photo-mechanical imposition supplies the means for making a composed press plate or a series of them for use on printing presses whereby the images are applied in predetermined register directly to the press plate, in any size, location, or position and without any intermediate duplicating means.

The art of photo composing combines upon one press plate or a series of plates the images produced by the numerous processes of reproduction known in the three general methods of printing.

The results are obtained by exact mechanical means and the use of predetermined register which permits the making of commercially used press plates for commercial printing presses, from which better color printing is obtained and longer editions are secured, with greater satisfaction and profit to the user of color advertising and the producer of color printing.

The results attained by photo-composed plates indicate the wide range of work that can be done economically in black and

[1] Secretary and Manager, Huebner-Bleistein Patents Co.

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

white or color, using typographic or lithographic originals, as well as varied processes.

All sizes of work, from cigar labels and stamps to large posters, including type forms with illustrations, are photo-composed successfully.

Photo-composed plates are preferably used on offset presses, producing better editions in less time than can be done on typographic presses or direct lithographic presses.

The producing of better editions, at less cost and in less time, is the reason why photo-composed press plates and offset presses are superseding the old methods of press plate making and printing.

### Mechanics of Photo Composing

Photo composing is accomplished by both methods of photography, by projection through a lens and by contact printing.

The projection method is used in the production of negatives intended for use in the contact printing machines. These negatives may hold two or more of the same image, repeated or combined with other images, forming group negatives.

The contact method is embodied in photo-composing machines, which produce the press plates on zinc or aluminum or on other desirable printing surfaces.

Twenty years of intensive application to practical work in going plants has developed four types of photo composers. These are being used for all kinds of work, of varied character and sizes.

The general functions of the various machines involve an image or negative carrier and a sensitized-plate carrier, relatively moved in one plane at right-angles. Clearance movement is effected by mechanical means to permit free travel to exposure locations without rubbing or damaging either the image plate or the sensitized surface.

Light action by an arc lamp is directed through an opening in the negative holder and passes through the light-conveyor openings of the negative for definite exposure periods. These exposure periods are limited by a motor-driven exposure controller so as to produce uniform results governed by light factor instead of time factor.

Close contact between the image and the sensitized plate to exclude any side light is forced either by direct mechanical pressure or by vacuum pressure during exposure periods.

A predetermined register system governs the successful results of photo-composed plates. It provides a complete system for computing exposure, location, and position of all images composing the printing form.

This is done by the coordination of the travel lines of the sensitized plate and the image plate, with known centers and dimensions of the image itself and of the register area covered. Precise register with any computed predetermined exposure location is obtained by the use of Swedish precision gage blocks, staggered to produce a rack 64 in. long with 1-in. spaces. The inch is divided into thousandths, indicated on a dial micrometer, which functions accurately and independently in any given or selected inch spacing of the gage blocks.

A special predetermined register device is used to place images in exact register with the travel lines of the moving sensitized plate or negative carrier. The register device indicates the travel lines of the photo composer so that the operator can quickly, conveniently, and accurately position the image to the zero point of the system, for computing the exposure location.

Adjustments are provided to maintain the travel lines at precise right-angles to each other. Accuracy is proved and maintained by hairline tests; that is, a single hairline opening on the negative is exposed on the sensitized plate and repeated three times, forming a continuous line three times longer than the line opening on the negative. This test is applied to both longitudinal and lateral travel lines. This proves accurate right-angle alignment, and provides the actual travel lines to which the predetermined register device is coordinated.

### Chemistry of Photo Composing

The chemistry of photo composing is so controlled as to produce durable printing conditions on the surface of the press plate.

Oxide coatings on metal plates are removed, and the surface is then neutralized as to acid or alkaline conditions. The surface is then rendered sensitive to grease by a sub-sensitizer solution, then sensitized with a coating for light action, and then dried. All this is done on a coating machine known as a whirler.

After exposure to the negatives the surface is coated with a greasy solution so balanced that when the solution is dry it will permit water to reach and dissolve the light-sensitive solution not acted upon by light. After development the printing plate surface is desensitized to grease by special solutions. These produce the printing condition needed by offset or planographic printing; that is, the image parts or dots accept ink from the ink rollers, and the grease-repellent surfaces of the plate surrounding the dots or ink-receptive parts accept moisture from the dampening rollers.

By carefully observing the rules governing the chemical action of a photo-composed plate on an offset press, successful editions up to 200,000 and more are printed, and a high quality of work is maintained at lower cost than by other printing methods.

Comparison as to time and costs of the old duplicating methods of stereotyping, electrotyping, and hand-transfer shows that photo-mechanical imposition or photo composing has the advantage of producing the work formerly done by all three methods in less time and with better quality, and certainly with lower costs in press plate making; and this augments the advantages in speed and lower costs of the offset-printing method.

Photo-mechanical plates, printed on offset or similar presses correctly coordinated, if the work to be done is intelligently planned, directed, and executed by trained operators, can lead the way in economical mass production of color printing, and in time will lead the way in text printing.

## Discussion

Edward B. Passano.[2] There is one statement in the paper which in my opinion should be qualified. The author states: "In relief printing these duplicates are made by using an intermediate means such as stereotyping and electrotyping between the original plates and the duplicate. In both of these methods the detail of the subject on the original plate is so changed by the transposition or transference through the matrices that it is not reproduced with fidelity."

It is the experience of the writer, and, generally speaking, it is the experience of the industry at large, that when a matrix is made by the lead process the electrotype is such an accurate reproduction of the original that there is no perceptible difference between the results obtained in printing from it and from the original engraving.

### Author's Closure

The author has no fault to find with that statement. It would apply to electrotyping just as it applies to hand transfers. There are thousands of hand transferers who think they can show better work than that made by machine. In fact, one man employed by the Methodist Book Concern says that he can make an electrotype that is better than the original. It is all relative; for in-

[2] President, The Williams and Wilkins Company, Baltimore, Md. Mem. A.S.M.E.

stance, if you are going to make a number of small repeated subjects, and if it is a matter of dollars and cents, you try to make eight or ten electrotypes exactly alike, so as to produce the edition economically. The photocomposer can do it better. However, there are varying limits in certain factors that creep into actual production of a series of repeated plates. I have never seen a set of, say, ten electrotypes made from one original plate that were exactly alike. They were close, but they were subject to criticism, especially in size, due to variable shrinkage in production of the individual electrotypes. Now, if you had a plate, say 12 by 14 in., on which groups of small subjects had to be accurately registered, and you followed the practice of electrotyping individual cuts and soldering them together, and from that grouped plate making a set of large electrotypes, it would be quite a job; it would take a lot of time, and that operation costs money.

In photocomposing we expose the required number of originals directly on the copper plate in exactly the position where they are needed, head up, sidewise, or head down in location. When that group photocomposed plate is finished, you make an electrotype of it, and there you have the advantage of speed, precision register, uniformity of result, and low cost.

We do not say we can make full-size press plates by photocomposing methods for the typographic press. In electrotyping there are limitations in size. We refer to the standard size of electrotypes for maximum size subjects that can be handled advantageously. We do say it is more economical to make a group of small subjects by photocomposing them than to group them by individual make-ready or soldering them together to produce a group plate and then making electrotypes from that group plate.

Just recently we decided to supply a small photocomposing machine for the photoengraver. The machine is about 4 by 6 ft. in size, mounted on one pedestal support. The photoengraver can then make small subjects in groups either directly on the copper or zinc plate or he can make contact group negatives for use in catalog color pages, small labels or small cartons from the photocomposed group plate. The electrotyper can make electrotypes for the printer which will save time in make-ready, and the results on the printed sheet will be more accurate than if the same job were produced without the photocomposing method.

If the photocomposer is used as intended, it cuts down make-ready time and eliminates the difficulty of assembling and registering a group of small originals or small electrotypes.

As to hand transfers, the author has seen some very good hand-transfer plates made by clever men, but it is not the usual thing. The difficulty with hand transfering is not only in getting the ink conveyors to correspond in size with the original plates, but in maintaining the size of the entire subject. There are other things to contend with; transfer paper varies the size of impressions with varied pressure when the impression is made. Hand transferring involves pulling impressions from various stones or plates.

In each case the pressure must be judged by the operator, and often there is a matter of days of time between the start and the finish of the job. I have never seen a hand-transferred plate that would take the place of the original plate, regardless of whether the sizes were alike.

# Report of Research and Survey Committee of the Printing Industries Division

## Organization Is Suggested of a Large Council of All Technical Men Interested in the Printing Industry to Discuss the Research Field in All Its Ramifications

By ARTHUR C. JEWETT,[1] PITTSBURGH, PA.

ON BEHALF of the Research and Survey Committee of the Printing Industries Division, I wish to present for your consideration two things: first, a problem affecting the printing industry; second, a plan for its solution.

All here recognize the magnitude and extent of the printing industry and the great variety of its related interests; in machinery for plant equipment; in innumerable kinds of supplies, such as paper, inks, textiles, adhesives, metals, etc. The briefest analysis serves to show that in this field there awaits solution a vast number of problems concerning the improvement of material qualities and operating methods, and the standardization of grades and sizes of material and equipment, and of working conditions in the printing establishment. The opportunities for profitable research are almost unlimited. It is obvious that no one organization or agency would alone show much progress in comparison to this extensive field.

There are, however, scattered about America from coast to coast many organizations and individuals who are making a localized attack on this large field. These researches vary from the scientific and basic to the superficial and slightly organized. When all these efforts are considered, there is still more left to be done than has yet been attempted. At the same time there exists a considerable mass of uncoordinated and unrelated research data that might be very valuable to many who do not even know of its existence. The problem is to secure a coordinated attack upon the entire field of research in its relation to printing and to make available to everyone interested a classified and indexed record of all that has been done to date. A formidable enterprise most truly, but one that may be successfully undertaken.

When the World War was being waged and many nations were called together in a supreme effort, a unified allied command became an unavoidable necessity. There are now many important organizations interested in the results of printing research, only a relative few of which are actively engaged in such work. If all could be enlisted to do a part and a centralized body could be organized as a coordinating and directing headquarters, the problem could be solved.

Your committee considers that this is not a fanciful dream or even an impractical idea. Our age and our country are both of the sort which makes such things possible. As a start, it proposes that a meeting of all technical men in the printing industry be organized, and that this be upon the occasion of the meeting of the Printing Industries Division at the next semi-annual convention of the A.S.M.E. Indeed, this meeting, with your approval, might well be the semi-annual meeting of the Printing Industries Division. It is estimated that there are at least four or five hundred such technical men.

The program of the meeting should be so organized as to reveal the opportunities for research, the capacity for research, the need of coordination, and the organization of a centralized coordinating and record bureau. A willingness to cooperate, to exchange data, etc., should be brought about and various organizations should be asked to assist in this work. There is, for example, already a representative organization whose aid would be invaluable in promoting such a plan.

In all this broad field of research the work of this Society should take two directions:

1 That of promoting research activities in the production field, and

2 Of attempting to bring about a coordination of the work of various organizations and to record and index all research work which is being carried on and all research data which is available, giving its location.

So far as actual research projects ought to be fostered by the Society itself, it is the opinion of the committee that the work should be confined to the production field as more directly related to mechanical engineering. It is also considered of great importance that everything possible be done to emphasize the importance of research work and to bring it prominently before all those whom it may affect.

In closing we ask: Do you approve such a meeting, as suggested, of technical men in printing? Will you do your part to enlist the interest of those other organizations interested in printing in which you are members or of which your companies are members? The Research and Survey Committee requests your support and suggestions.

Being put as a motion and seconded, it was carried and referred to the Executive Committee of the Printing Industries Division.

---

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

[1] The personnel of the Research and Survey Committee of the Printing Industries Division is as follows:

Arthur C. Jewett, Chairman; Director of the College of Industries, Carnegie Institute of Technology, Pittsburgh, Pa.

Francis H. Bird, Professor of Commerce, University of Cincinnati, Cincinnati, Ohio.

James R. Blaine, Mechanical Engineer, Miehle Printing Press Manufacturing Company, Chicago, Ill.

Edward W. Dean, Chief Engineer, Duplex Printing Press Company, Battle Creek, Mich.

Don A. Johnson, Superintendent, Empire State Printing School, Ithaca, N. Y.

J. Horace McFarland, President, J. Horace McFarland Company, Mount Pleasant Press, Harrisburg, Pa.

Edward T. Miller, Secretary, United Typothetae of America, Chicago, Ill.

John Clyde Oswald, Managing Director, New York Employing Printers Association, Eighth Avenue and 34th Street, New York, N. Y.

James T. Peto, Mechanical Superintendent, The Press-Guardian, Paterson, N. J.

M. E. Powers, Printing Engineer, Pettingill, Inc., Chicago, Ill.

Edward O. Reed, Technical Director, Government Printing Office, Washington, D. C.

R. F. Reed, Director, Department of Lithographic Research, University of Cincinnati, Cincinnati, Ohio.

W. E. Sooy, Secretary and Plant Manager, Michigan Carton Company, Battle Creek, Mich.

# Photography as Used in Color Reproduction in the Graphic Arts

## The Three-Color Theory of Vision—Making Photographic Materials Sensitive to Colors—Natural-Color Photographs—Color-Separation Negatives—Printing Processes—Modern Four-Color Printing Presses and Their Interesting Devices

By A. J. Newton,[1] Rochester, N. Y.

***Indications are that the demand for color in the graphic arts, produced by means of photography, will continue to increase, and this means that as the fundamental principles appear to be well established, further improvements will be made in machinery and materials and the skill in using them; and particularly in adjusting practice as closely as possible to theory, so that color reproduction, while maintaining the highest possible quality, will be produced more speedily and more economically.***

In order to cover his subject in the limits of a paper, the author must necessarily omit a great deal of detail. The need for condensation will be seen when it is stated that a recent compilation of merely the history of three-color photography is a volume of 747 closely printed pages, treatment of all photo-mechanical processes being reserved for a further volume.

Color is not an objective thing in itself, it is a sensation and purely subjective. In other words, we receive an impression of color by reason of the varying reflections and absorptions of the different wave lengths which constitute white light. These wave impulses affect the mechanism of our eyes and brain, and according to their differing frequencies give us the impression of color.

Our yardstick for color is the spectrum, which was discovered by Newton in 1666. A spectrum is produced by passing a narrow beam of light through a prism, which refracts and disperses it. As white light is made up of a number of differing wave lengths, these are differently refracted and each wave length has a different color. This is ultimate, as any further analysis of any part of a spectrum does not yield anything different. So all colors can be referred to the spectrum, as they must either consist of one of the pure spectral colors or mixtures of them.

When light falls upon any substance it is either totally absorbed, in which case the object looks black—for example, a piece of black velvet; totally reflected, in which case it looks white, as freshly fallen snow; or selectively absorbed—that is, some portion of the light is absorbed and the remainder reflected, this reflected mixture of the non-absorbed parts of the spectrum giving the characteristic color. Thus, grass is green because the major portions of the blue and red are absorbed, and the remainder which is reflected is predominantly green.

### The Three-Color Theory of Vision

The nature of the mechanism in our eyes that gives rise to color sensation when appropriately stimulated, is still the subject of investigation and dispute. The most generally accepted hypothesis is that our eyes have only three sensations, one being stimulated by blue-violet light, one by green light, and one by red light. When all three are stimulated simultaneously we get white or gray, according to the intensity of the stimulation, and of course nothing, or black, in the absence of stimulation. On this theory we see all colors from these three, either alone or in mixture. For example, when we see a yellow it is because both the red and the green sensations are stimulated at the same time together, and this result gives us the effect of yellow in the brain.

This hypothesis was put forth by Dr. Young in 1801, and was confirmed by Helmholtz and many others after him.

In order to prove that the three-color theory of vision was correct, three narrow portions of the spectrum were isolated, one each in the red, the green, and the blue-violet, and it was found that by means of these, either alone or mixed in suitable proportions, all the colors of the spectrum could be approximately matched, provided they were diluted with white when necessary. While it does not matter in the least in practice what the mechanism of the eye is, provided any color can be approximately imitated by one or more of three, either alone or in mixture, it was this theory that led Clerk Maxwell to reason about three-color photography and to take the first step toward the current practice.

From the very beginning of the use of photography—not yet a century ago, because it was in 1839 when the first daguerreotypes were produced—it was hoped that color might be reproduced by means of photography, but it was not until 1855 that the first definite scientific principle was enunciated by Clerk Maxwell, then an undergraduate of Cambridge University and only 25 years of age.

In a paper communicated to the Royal Society of Edinburgh in that year, Maxwell said:

> Let a plate of red glass be placed before the camera and an impression taken. The positive of this will be transparent wherever the red light has been abundant, and opaque where it has been wanting. Let it now be put in the magic lantern along with the red glass and a red picture will be thrown on the screen. Let this operation be repeated with a green and violet glass, and by means of three magic lanterns let the three images be superposed on the screen. The color on any point of the screen will then depend on that of the corresponding point of the landscape, and by properly adjusting the intensities of the lights, etc. a complete copy of the landscape as far as visible color is concerned will be thrown on the screen. The only difference will be that the copy will be more subdued or less pure in tint than the original.

In 1861 Maxwell had the experiment prepared with a bow made of colored ribbons at the Royal Institution, London, and said that given a suitable sensitiveness to the red and green, the reproduction would have been a truly colored representation of the ribbon. It was not possible to make a correct reproduction then because there were no such things as color-sensitive plates as there are today, for at that time they were confined to the use of wet collodion. Ever since that time the theory, while not unchallenged, has remained unshaken, and all our color practice is based upon these principles. And in order to attain to the present quality of color work there has been no change in the theory but a great deal of advance in regard to the materials used, particularly in the filters, in the color sensitiveness of the photographic sensitive plates, and in the skill of the users of these materials. The recently introduced "Kodacolor" process of

[1] Engraving Department, Eastman Kodak Company.

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

making amateur motion pictures in color is precisely the same in principle as Clerk Maxwell's first experiment.

Photographic materials are sensitive only by reason of their absorption of light, which in some way not yet completely understood disturbs the equilibrium of the particles of silver halide and renders those affected by light in this way capable of development.

### Making Photographic Material Sensitive to Colors

The law concerning this is known as the Grotthus-Draper law, and states that "only those rays of light which are absorbed can produce chemical action." Now photographic materials as manufactured are none of them susceptible to the chemical action of light rays in the same proportions as our eyes. Generally speaking, they are much more sensitive to the violet-blue rays than to any others, whereas our eyes are most sensitive to the yellowish green rays of about wave length 550 $\mu\mu$. Photographic plates are also sensitive to the ultra-violet, which we cannot see at all. The wet-collodion plate with which Clerk Maxwell worked has at least half its total sensitiveness in the ultra-violet. In these circumstances the problem has been to make the photographic material sensitive to all colors as nearly as possible as the eye is sensitive to them. It should be stated, however, that provided enough exposure is given, any color can be recorded on a non-color sensitive plate. Even a wet-collodion plate will record red if exposed 7200 times longer than it normally is. This, however, is not practical, and so it was a great advance when it was discovered how the plate could be made to absorb green and red light rays.

In 1873 H. W. Vogel was making photographs of the spectrum on all sorts of plates. He had one plate from England which had been stained with a yellow dye in order to prevent halation, that is, light penetrating the film and being reflected back from both surfaces of the glass on which it was coated. Vogel noticed that this photographed the green, which other plates did not. He thought this might be due to the dye, so he washed it out and tried another photograph, and, as he expected, there was no effect then in the green. He then tried staining plates with other dyes and succeeded with several, and so introduced the first color-sensitive plates.

Since that time many dyes have been found which are suitable for the purpose, though more is necessary than the mere fact that the dyes will absorb light of the particular color it is desired to photograph. The dyes mostly used to make the commercial orthochromatic plates sensitive to green and yellow are eosin and erythrosin, the use of which was patented in 1883.

In 1903 a dye known as ethyl red was discovered by A. Miethe and A. Traube, and this was the first of the modern dyes produced especially for the purpose of sensitizing photographic plates and which have since become universally used to make our present panchromatic plates.

Dyes have also been developed which sensitize plates even far into the infra-red. Some of the best of these dyes have been produced in the organic chemical laboratory of the Eastman Kodak Company. But even when plates are as fully sensitized as we know how at present, they still do not photograph the spectrum or colors in the same degree of luminosity as the eye sees them, and so a filter to cut down the excess sensitiveness to which the plate is subject has to be used when we are making photographs to give a monochromatic rendering in true values.

In the case of three-color reproduction the filter is used to cut off all other colors except the one which it is desired to record; thus the blue filter transmits the blue but absorbs the green and the red and prevents them reaching the plate; the green filter transmits the green but absorbs the blue and the red; and the red filter transmits the red but absorbs the green and the blue.

As in most cases we cannot make color-separation negatives suitable for the preparation of printing surfaces direct from the objects themselves, such negatives are made from colored representations thereof, such as paintings in oil or water colors. But this is not so realistic as photography itself, so there is gradually growing up a practice of making natural-color photographs to serve as originals for reproduction by photomechanical printing.

### Methods of Making Natural-Color Photographs

There are at present only two main methods of making natural-color photographs: first, the making of three-color transparencies on glass such as Autochrome or Agfa plates—so-called "screen plate methods;" and secondly, the making of a photographic print on paper in three colors. The most successful of these so far are the three-color-pigmented gelatin prints ("carbon process") and the three-color "Carbro" prints. In the latter a bromide print is treated so that it insolubilizes the pigmented gelatin-carbon tissue where required. Lastly there are imbibition methods such as the Pinatype and Jos-pe, in which a gelatin surface is dyed in proportion to the exposure and such dyes are imbibed from the respective three plates by a plain gelatin-coated paper in exact superposition.

To get good three-color paper prints is at present extremely difficult. They are therefore very expensive and as yet have not come into wide use, so that, as said above, most of the colored illustrations seen in magazines and books are reproduced by photographic means from artists' originals.

The transparency processes are called "additive" processes because they add the three colored lights together, while the color prints on paper are called "subtractive" processes because, starting with the white paper reflecting all colors, the dyes or pigments placed on it "subtract" from these the color not required. All photomechanical color processes are "subtractive."

### Color-Separation Negatives

To reproduce any object or a painting in its natural colors, it is necessary to make what are known as color-separation negatives. That is, a photograph is taken of all the reds reflected from the object, another of all the greens, another of all the blues. Frequently a fourth photograph is made giving a monochrome representation of the object with all the tones in their respective luminosity values, for printing in a black or gray. This is not actually necessary for color reproduction, but is doubtless done to save the trouble which the extreme exactitude of three-color demands. Small errors are covered up by the black plate, and so it is generally used. And when black text has to be used with the illustration it can be excused.

From these separation negatives, positives are made, and from these positives, negatives have to be made that are suitable for making a printing surface—though in the case of some printing processes the original separation negatives will do, e.g., collotype or photogravure.

When the printing surfaces are prepared they are printed in inks which are complementary to the recorded light. Thus the printing ink for the red record is a "minus" red, or green-blue; that for the green record is a "minus" green, or red-blue (magenta); and that for the blue is a "minus" blue, or a red-green, which is a yellow. The reason for these "minus" colors may be better realized if we consider a black-and-white photograph. The record on the negative is of the white of the subject photographed. This negative is now printed on sensitized white paper. The density of the negative representing the whites prevents light from reaching the paper so that it remains unchanged, but the transparent parts of the negative representing absence of white allow light to go through and darken the paper there. In other words, we have an absorbing material for white, or a "minus" white.

These color inks should not only completely absorb the colors which have been recorded by the photograph but should also completely reflect the other regions of the spectrum since some other color may have been present on the original. No such ideal inks are available as yet, and it seems doubtful if they ever will be. In order to correct the errors shown in any purely mechanical reproduction by reason of the imperfect inks or other cause, retouching by hand has to be resorted to, and this is what makes color reproductions so expensive.

### Printing Processes

Printing processes can be divided into three classes; (1) the most common, *relief*, that is, the familiar halftone and all letterpress printing; (2) *intaglio*, which is the exact opposite to relief, the design which prints being cut into the surface, represented by rotogravure and rotary rotogravure; and (3), *surface*, represented by all planographic processes such as collotypy and photolithography.

The taking of the original negative is the same in all these methods, but according to the process desired a departure is made in preparing the printing surface.

In the case of relief printing the effective gradation of tone has to be secured by means of ink of the same strength wherever applied, put on to a paper ground of one color only. Therefore the effect of tone can only be secured by varying the distribution of ink as compared with the paper. This is attained by splitting the picture up into minute dots which vary in area according to the tone required. Thus in a light tone the ink dot is small and much white paper shows. In a middle tone there are about equal proportions of ink and paper, and in a shadow tone the dots are large and the amount of white paper showing is very small. In order to produce these dots the negative is made behind a cross-line screen so placed in the camera that the amount of light reflected from the original at any point is represented by a correspondingly sized dot. The dots are so small they cannot be individually distinguished by the naked eye, but appear as blended tones. The same sort of negative is produced for the planographic method, but the intaglio method is different because the effect of tone in this case is secured by varying depths of ink for varying tones, so that in the shadow the ink is piled up and in the high lights there is scarcely any. Most paintings and small objects without much relief can even be reproduced "directly" by using the color filter and the cross-line screen at the same time so that the one negative is both color-separated and grained ready for preparation of the printing surfaces without the intervention of a previous negative and positive; but this cannot be done with subjects of much relief or having very great contrast—they must be photographed in two stages.

When the printing surfaces are secured by whatever method, they have to be printed very exactly in register. The usual order of printing is the yellow first, the red second, and the blue last. The reason for printing the yellow first is because the yellow is a more opaque ink as a rule than the other two, and theory demands for the best results that the inks should be absolutely transparent. As no inks whatever are completely transparent there is always a slight preponderance of the last printing, and it is better to have a preponderance of blue for most subjects than a preponderance of red. If the average yellow ink were printed last it would blot out the other two colors, and there would be very inefficient reproduction.

### Modern Four-Color Printing Presses

In latter years, owing to the speed with which the work is required, inks have been developed that print wet, and the paper goes in at one end of the machine and comes out at the other completely printed. The most notable of these machines are those at the Curtis Publishing Company's plant in Philadelphia. These are the large four-color Cottrell printing presses which print the *Saturday Evening Post* and the *Ladies' Home Journal*. These presses are most remarkable ones as they are so built that they take the paper from the web and carry it on through the press on the impression cylinder, and impressions are made from the yellow, red, blue, and black plates, one immediately following the other. These presses run at about 55 revolutions a minute. In the new type they carry two sets of plates, giving a much larger production. They have a great latitude since they are always available for running black on each side of the sheet, or two colors on each side, or two colors on one side and four colors on the other. It is necessary to have an ink that is absolutely correct for this type of press, the yellow being tackier and having the ability to pull the red ink from the red plate, the red tackier than the blue, and the blue tackier than the black. This ink condition is one of the very vital points. Formerly great difficulty with color printing wet was the trouble experienced with offsetting when the sheets came off. But there is a most ingenious attachment to this press which prevents that. As a finished sheet comes through it is coated over with an extremely fine spray of liquid paraffin. This immediately solidifies, and when the next sheet is delivered it rests upon a minute amount of paraffin rather than on the ink, and so there is no offset. It took some time to adjust this accessory arrangement to the exact amount of paraffin necessary, but now it is so used that it does the work without any disadvantage whatever.

All the plates for printing by this press have to be specially prepared in regard to their overlay and underlay. The electrotypes must carry the treatment themselves to take the places of make-ready that would be necessary on the ordinary printing press, because each plate strikes the same spot on the impression cylinder. This treatment consists of lowering the lights of the electrotypes by means of paper-cut matrices impressed into the electrotypes while they are quite hot.

### Rapid Growth of Color Printing

Another point in regard to printing color work or indeed any halftone work is the very much greater need in it for accuracy and precision. An engineer, Mr. Claybourn, of Milwaukee, who has devoted many years to demonstrating this, is building presses now which, if the halftones and electrotypes have been accurately made, will give perfect results without any make-ready at all. The growth of color work in recent years has made necessary all these improved printing presses, and, although one hardly realizes it, the growth has been really astounding. For example, the editor of the *Saturday Evening Post* recently stated that in 1917 that journal carried only 417 pages of color advertising, whereas in 1927, ten years after, it carried 2864 pages. The *Ladies' Home Journal*, another of the Curtis publications, carried only 198 pages of color advertising in 1917, whereas in 1927 it carried 719 pages. Four-color was first used in the *Saturday Evening Post*, October, 1924. In 1927 it carried 869 pages in four colors. Color reproduction is extending in all the other magazines in exactly the same way. In fact, there would be extremely little of it at present but for the application of photography to the problem. The various hand processes, wood engraving, lithography, or mezzotint or stipple, in color, are all too slow and costly to the modern idea, besides they do not give the realistic impression that photography does, so that almost without exception the colored reproductions which we see everywhere in such increasing quantities all depend upon photography.

As our knowledge becomes more widespread, there is an attempt to produce inks nearer to the theoretical requirements and also to use them in a standardized way. Hitherto many

ink makers have had their own standards of ink, and many engravers have used whatever inks they thought would give the nearest approach to the colors of the original with the least work on their part. Naturally, when a printer receives a number of engravings from different firms and different inks have been used, he cannot get a satisfactory result from all of them if they are printed together on the same press. This has been so disappointing to the advertisers that at last they have joined forces with the American Institute of Graphic Arts, which has had this subject under consideration for many years, and they are now insisting upon standard three-color inks being used. Though these may not be ideal, or the best that could possibly be obtained, it will be a great deal better to use them than to employ various kinds of ink and get various results in consequence when printing in different publications.

So far the author has dealt mainly with relief printing, but the same principles apply to planographic printing (offset, lithography, collotypy) and intaglio (photogravure and rotary photogravure).

### Interesting Devices Developed for Color-Printing Machinery

The increase of color reproduction has led to the development of remarkably interesting machinery in these processes, particularly the step and repeat devices to multiply the images in the reproduction of subjects requiring very large editions, as is often the case in lithographic printing. Sometimes these devices are cameras which can photograph the same thing many times on one plate, but more usually they take the form of machines which enable the same negatives to be printed on a large printing plate several times in the exact positions required. These machines have to be of the utmost precision in order that the color prints shall accurately register one on top of the other when printed on the press, and enormous effort and large sums of money have been spent on perfecting them.

Color has been applied to rotary photogravure for over a dozen years, but it has not become very common so far. Some newspapers, notably the Chicago *Tribune* and the New York *World*, use it in their Sunday supplements, and sometimes very successfully; but the difficulties in securing exact register due to the processes used in preparing the copper cylinder and printing from the web are very great, and it is also difficult to secure approximate fidelity to the original owing to the nature of the inks without excessive retouching, which is expensive and time consuming.

The indications at present are that the demand for color in the graphic arts, produced by means of photography, will continue to increase, and this means that as the fundamental principles appear to be well established, further improvements will be made in machinery and materials and the skill in using them; and particularly in adjusting practice as closely as possible to theory, so that color reproduction, while maintaining the highest possible quality, will be produced more speedily and more economically.

# The Field of Lithographic Printing

## A Brief Survey of the Various Processes, Materials, Machinery, and Operating Methods Employed in Lithographic Printing, With Special Reference to Multi-Color Work

By GEORGE C. VAN VECHTEN,[1] ROCHESTER, N. Y.

IN THIS age when color is king and is reflected in every article which we purchase, the demand for lithographic printing has grown by leaps and bounds. Color causes reactions which penetrate to the subconscious mind, creating a desire on the part of the individual to possess. With the presence of interest caused by color and word pictures, action prevails, and the effect is their urge to buy.

Window trims are more colorful, the attire of the nation's ladies is made more attractive and beautiful, the decorations of the product of the automotive institutions are a delight and harmonize with this age of contrast. By the use of lithography and color printing our advertisements are a distinct charm. The food containers on our grocers' shelves, with the colored reproduction of their contents, represent a condition which is entirely psychological. However, the housewife would not think of purchasing a commodity having a simple label, notwithstanding the fact that the contents of the container having the simple label may be superior to those of its gaudy companion. There is a possibility of the situation's being overdone, however.

The graphic arts have had a serious problem before them to keep pace with the desire for gaudily dressed containers and the blaze of color connected with advertising. At the present time there is an appeal for reform to eliminate the riot and reduce the problem to a sound and economic basis. The desire for innovations and the madness for style is leading to a condition due to freakish shades and tints that is baffling to lithographers and ink makers. A reform in this direction would be a material asset, and would greatly improve the economics of the situation.

### The Invention of Lithography

The invention of lithography by Alois Senefelder, who was a studious and ingenious man, was an achievement upon which the lithographic industry of the present day is based. The fundamentals of the art still exist notwithstanding the development of high-speed offset presses and photo-composing methods.

Senefelder was a restless genius and an experimenter dabbling in hundreds of different ways. First he practiced reverse writing. Afterward he found that by writing with an English pencil on suitable paper he could offset his writing on to stone. Having the stone for his original he was able to transfer the image to other mediums and multiply the creation. Finding a suitable transfer paper was one of the difficult problems he had to solve. Next in line with Senefelder came the problem of a proper printing press for the development of his work. The first press resembled a washing machine, involving a wringer or roll and a handle. From this crude beginning we have an industry which ranks eighteenth in importance today. Due to Senefelder's invention and the desire for color, the market for lithographic products has been created.

The question which comes to the mind of the average layman is this: Why the necessity for lithographic printing when color reproduction can be successfully accomplished by letter press? The principal reason for the existence of lithography is that on account of printing from a zinc or aluminum plate of large size (45 in. × 65 in.) it is possible to produce large quantities of beautiful work cheaply. One of the serious drawbacks to multi-color printing by letter press is the costly "make-ready." Preparing the lithographic plate is much more simple, particularly by the use of photo composing, step and repeat machines, or mechanical transfer.

### Lithographic Methods

A lithographic printing institution comprises a creative department where beautiful designs are developed and offered to the market; a photo-composing or hand-transfer department where these designs are reproduced for commercial production on the printing plate; and a printing department where by means of the planographic press, the image is reproduced in large quantities. The planographic process, which is described later, depends on both attracting printing ink to the parts of the image where it is required, and repelling it, through the antagonism of grease for water, where it is not wanted.

### Man Power

Beginning with Senefelder's invention in 1796, a craftmanship has been developed which has reached a high state of perfection. These highly trained artisans have been imbued with the pride of achievement, which is a very desirable attribute and reflects the standard of the institution with which they are affiliated. It is doubtful whether this profession will ever be materially affected by the development of modern methods, or replaced by the camera or by mechanical and other means.

This is, however, only as regards the creative function of the art, for in the production end of the business it is possible that the personnel may succumb to the ills of mass production. By that the author means that we shall develop press operators, cutting-machine operators, inspectors, and such employees as are concerned in handling the equipment, but due to proper control methods the preparatory work will be taken care of by other means. Under the present system the lithographer handles most of the details. Under the new scheme of things he will be familiar only with the specific function with which he is identified. The pride of achievement may be lost in the transition, and it will then be necessary to offset this condition by training. Executives are realizing at the present time the necessity for training, and arrangements have been made with the principal seats of learning in our leading cities whereby foremen, craftsmen, and executives may be afforded instruction in their particular branches.

### Production Control and Wage Incentives

In the reproduction departments, however, modern production methods have made some inroads. The lithographic industry has been very slow to adopt scientific management, and the majority of establishments are still functioning under the older methods. This is particularly true in connection with all departments except the mechanical. In the press field considerable progress has been made.

Due to the severe competition which prevails at the present

---

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

time and which will continue to command extreme effort, wage-incentive systems and production control will be necessary if the individual plant is to survive. The trend at the present time is to utilize photo-composing methods, high-speed offset presses, and long runs providing the greatest area of salable product with the minimum of waste.

The industry has been slow to adopt material-handling methods and as a consequence there are great possibilities in adopting the Ford plan and thus increasing production per man-hour many fold. In order to adopt these measures, however, it will be necessary to practically revolutionize the industry. It is the tendency at the present time to carry large inventories of raw and semi-finished material requiring a large investment and much floor space. This condition prevents a rapid turn-over of capital and is a serious handicap in the competitive market. Most of the establishments have developed from a modest beginning and as a result it was not possible for them to give any thought to the flow of raw and finished materials or to building layout. To remedy this situation will require a comprehensive study of methods to eliminate large inventories and excessive floor space. One of the serious drawbacks to the continuous-flow system is the large floor area required for stock in process. Where presses are running in series on a color program the proper coordination of the colors involves a time element necessary for the oxidation of lithographic inks. It would be necessary to overcome this condition by the adoption of conditioning apparatus to promote continuous flow of materials and oxidation of inks.

Proper plant layout is one of the prime essentials if a production-control system is to be inaugurated, and offers an opportunity for the engineering profession to develop the field. It is only recently that sound engineering principles have combined with inventive genius. The modern press is constructed by the aid of jigs and fixtures, the result being that the parts are interchangeable. This was unheard of a few years ago. With the adoption of modern methods within the industry the problems of foreman training and human development will become much more pronounced.

One of the basic materials upon which the lithographic industry depends for its existence is paper composed of cellulose fibers which are hygroscopic in nature and which relies upon the uniformity of the moisture content of the atmosphere to preserve its fitness for the process. It is advisable for the engineer to utilize synthetic weather or air-conditioning systems embodying refrigeration. One of the serious problems that the lithographer has to face is the expansion and contraction of paper fibers due to the variation in the relative humidity of the atmosphere. This condition is most serious during the months of July and August when the outside dry bulb is high. Without the use of an air-conditioning system and refrigeration apparatus considerable loss in production is experienced. This is also a contributing factor to the waste problem. It is often quite necessary for plants which do not utilize conditioning systems to shut down on very humid days. During the winter months, however, a reverse condition prevails. Where extremely low relative humidity exists on account of the necessity of heating the buildings, an air-conditioning system is a tangible and profitable investment and can be utilized practically during the entire year.

The tendency at the present time is to condition the paper warehouse or storage room, maintaining a uniform humidity and acclimating the incoming paper stock to that condition by individual paper-conditioning or curing machines. This element of production control is further augmented by maintaining the same relative humidity in the press and other process departments. The use of such equipment, however, is not a cure-all. There are a number of other variables which offset the situation. One of the conditions which has a bearing on the problem is the mechanical stretch of the paper and this is more pronounced in connection with the direct printing process than with the offset method. The offset press, however, has reached a much higher state of development and the coordination of printing surfaces is under a much better control than that effected by the direct-press method.

## Materials

As stated before, paper is one of the principal basic materials used in the printing industry, and exists in a number of forms carrying the trade names of book, blotter, tissue, board, bristol, manila, and others. These in many cases are subdivided into grades and classes. One of the necessary requirements for lithographic printing is a paper having a smooth surface and uniform thickness. This is accomplished by the use of paper calenders. In order to provide the proper printing surface it is customary in many cases to coat the surface of the paper with a material composed of china clay, blanc fixe, casein, and other coating ingredients. This coating process creates an ideal printing surface. However, many times it is difficult to secure a perfect impression on account of tinting trouble, particularly in connection with presses which print four or five colors at the same time. It is necessary to develop special coating materials for this condition. Second in importance in the line of materials are inks, the variety of which depends upon the degree of standardization of colors. An institution producing art subjects will apply as high as twenty colors to secure the necessary color values according to the temperament of the artist, while the regular commercial house usually standardizes on a maximum of eight or nine.

The colors are divided into groups as follows:

*Yellows*
1 Chrome Yellow
2 Chrome Orange
3 Yellow Lake

*Blues*
1 Milori
2 Prussian
3 Bronze
4 Ultramarine
5 Blue Lakes
  *a* Peacock
  *b* Oriental
  *c* Alkali

*Greens*
1 Chrome Green
2 Green Lakes

*Reds*
1 Mercury Vermilion
2 Red Lakes
  *a* Madder
  *b* Para Reds
  *c* Toluidines
  *d* Lithol Reds

*Purple and Violet Lakes*
1 Permanent
2 Fugitive

*Orange Lakes*
1 Persian
2 Permanent

These basic materials are used in conjunction with a large number of driers, reducers, softeners, and other substances which in compounded form produce the beautiful shades and tints used for the printing operation.

Paper and ink are two of the most essential materials used, but are supplemented by a large number of chemicals and supplies, such as chromic, nitric, and phosphoric acids, which are used as etches, rubber blankets, leather shins for covering form rollers, molleton flannel, canvas, rubber-covered rollers, gum arabic, stearin, photographic supplies, lithographic stones, etc.

## Machinery

Inventors identified with the industry for many years endeavored to duplicate by mechanical means the fundamental

principles developed by Senefelder and were successful in devising the stone press which followed in sequence the hand press. They applied a reciprocating motion to a movable bed designed to receive a large stone upon which the image was transferred in reverse. This bed moved back and forth underneath a cylinder which revolved in unison with it, and upon the periphery of which the paper was attached by means of grippers. To insure perfect register the gear and rack were coordinated by means of a stop tooth which came into contact with the rack on the bed. This allowed the bed to come to the same position each revolution. The stone press embodied the direct printing process and was the prevailing method used until the invention of the offset press by Ira Rubel in 1904. This invention was identified with the tin printing industry until about ten years ago, when it was adopted by the paper printer. The direct-printing method enjoyed a long period of prosperity, and utilization of this type of equipment was the medium by which the prominent lithographers of today established themselves. The process was highly developed and it became possible to print as high as five colors at one time. Two presses of this type were designed and constructed, and are in operation successfully today. Four presses were also built which would print four colors at one time. These are also in operation at the present time.

Lithographic presses are divided into two general types, direct and offset. The direct press is one in which the impression is made directly by the aluminum or zinc plate on the paper or medium upon which the design is to be printed, and is the oldest of the two types in general use today. The offset press is equipped with an additional cylinder called the "blanket" cylinder, upon which a rubber blanket is stretched over the printing surface on the periphery. In the operation of this press the image is transferred from the aluminum or zinc plate to the rubber blanket and in turn to the paper. By this method a more beautiful reproduction is possible, and as in the manufacturing of presses at the present time the tendency is to produce offset machines, the direct types will soon cease to be built.

The direct press has advantages where large quantities of ink are required for poster work or where a heavy background is desired on label work or jobs of this type. One of the drawbacks of the direct press was the absence of bearers, and without this medium the pressman had considerable difficulty in coordinating his printing surfaces. Another difficulty experienced in the operation of the standard types of direct presses was the method of sheet delivery. The early types embodied the fly delivery, which was fairly successful. The fly delivery consisted of a series of hardwood sticks ranging from 30 in. to 48 in. in length according to the size of the press. These fly sticks were tapering through their length and were equipped with steel star wheels at intervals of about 6 in., arranged in a vertical position on a horizontal axis in a slot. These sticks were supported at the base by a shaft which caused them to travel through an arc of about 90 deg. They received the sheet of paper from the delivery cylinder and delivered it to the pile where the sheets were stacked.

It had disadvantages, however, due to the fact that the work was delivered to the fly with the printed side down. Further, it was necessary to use fly strings on the delivery to carry the sheet down to the proper position for the fly sticks to receive it. These strings also contributed their share toward producing work of poor quality. This type of delivery was responsible for the slower speeds in the operation of these presses, and this condition prevailed for a number of years until the chain and gripper delivery was developed. This improvement embodied two methods of handling the material in process: First, the racking feature, where the printed sheets were delivered to a rack which was inserted under the delivery grippers. These racks held about fifty sheets, and were quite necessary on presses printing three or more colors on account of the danger of offsetting. This feature was also a material aid in the oxidation of the inks. Secondly, the possibility of stacking the work on platforms which could be handled by an elevating truck. This type of delivery required an elevator, which was embodied in the design of the press.

With the desire for greater speed the press builders developed the chain and gripper delivery, which is used by practically all press manufacturers at the present time. In most instances this increased the speed of the press, but the marking of the sheets still prevailed and a poor quality of work was produced. As in the former case, this was due to the fact that the work was delivered with the printed side down to delivery conveyor. The sheet was reversed finally and arrived on the pile right side up. Many presses of this type are in operation today, but they are not adapted to work having heavy backgrounds where high quality is required. This defect was overcome later, however, by the adoption of the extension delivery such as is used in conjunction with the modern offset press.

In the modern extension delivery the sheet is delivered from the impression to the delivery cylinder underneath the press; passes below the operator's platform and is delivered right side up on a platform for stacking.

In the older chain-delivery types, the sheet was transferred upside down from the impression to the delivery cylinder near the top of the press.

Competition in design was responsible for many improvements as the field developed. This was particularly accelerated by the use of electrical equipment which made it possible to employ individual drive, dynamic braking, inching, reversing, and other features. This also made it possible to trip the press automatically when a sheet of paper failed to register at the guide. Competition in press building was also responsible for the development of the automatic tripping of press cylinders and roller motions, which eliminated lost time and increased production.

Labor conditions and the desire for better register of colors created a field for the automatic feeding of presses, and at the present time this is standard equipment. The automatic feeder embodies many features which prevent lost time. It comprises several functions such as sheet separation by means of a platen, a lifting and forward movement by means of suction and pressure under the sheet, micrometer control to insure one sheet's being delivered at a time, a tripping device in case a sheet failed to come up to the guide correctly, as well as other features.

With the adoption of the offset press by the paper-printing industry a machine has been developed which embodies sound engineering principles and skilled workmanship. In the early days of the press builder the designer was usually more inclined to be an inventor than an engineer, which resulted in a lack of standardization. The offset press of today has been constructed for the purpose of mass production with a high standard of quality, quick make-ready, and automatic devices to eliminate lost time. It is possible to operate the latest types up to and including 4000 per hour. By the use of suitable bearers the printing surfaces are under control and slippage is practically impossible.

The possibilities in the offset-press field are unlimited and it would be difficult to predict as to developments in the future. Except in one or two special cases, two colors are the most that have been successfully used on the sheet-feed press. A German manufacturer has been successful in building a four-color web offset press which is in use at the present time in Australia, and one of the representative press manufacturers has expressed a willingness to build a three-color sheet-feed offset press for a special line of work. The various lines of machinery which are

involved in the finishing operations have also kept pace in improvements and automatic features.

The finishing process utilizes some of the following equipment: embossing presses, folding-box machinery, and scoring and creasing, stitching, and cutting machines. There has been a desire on the part of the cutting-machine designer to build a machine having greater accuracy and strength. At the present time German manufacturers are placing cutters on the American market which are massive in structure and embody automatic features such as spacing devices and adjustable clamping to allow for differences in thickness of the stock to be cut. A new safety trimmer has been designed which adapts itself very effectively to the continuous flow of stock. This cutter differs from the conventional type in that the stock to be cut is fed at the front side of the machine and delivered at the back. It is particularly successful in connection with the chopping operation.

Folding-box gluing machines have been developed which have a production as high as 700,000 boxes per day. Formerly 250,000 was considered a good record.

The scoring and creasing, stitching, folding, and other machines have been greatly improved to promote greater production.

### Research

Nearly all of the branches of industry which process or manufacture the raw materials used by printers are affiliated in some way with some institution involving research. The Pulp and Paper Makers' Association have identified their activities with the Forest Products Laboratory of Madison, Wis., a branch of the Department of Agriculture. The manufacturers of lithographic inks and the lithographers have subscribed to the Lithographic Technical Foundation. This is operated under the auspices of the University of Cincinnati and is directed by Prof. Robert Findley Reed.

The manufacturers of lithographic and spirit varnishes are either connected with some research bureau or conduct their own. This is true also of the manufacturers of the less important materials which enter into the operation of a plant. Paper, historians tell us, was made by the Chinese some five thousand years ago, and has been gradually improved up to the present time. Considerable research work has been conducted and constructive developments made. In spite of all this, the lithographer feels that the surface has hardly been scratched, and that the paper manufacturers have before them tremendous opportunities for advancement in the art.

In this age of automatic packaging machinery the label manufacturer has before him a serious problem to produce a label that will function properly. This involves paper of proper tensile strength, flexibility, folding quality, glue penetration, surface and absorption qualities, as well as better appearance. These requirements are severe, and in some grades of paper the character of the cellulose fiber plays an important part in the formation of the sheet. Paper manufactured from the northern woods has longer fiber than that from the southern woods, and in the manufacture of gum-label stock this is a very necessary requirement. The fiber formation and use of southern wood pulp provides a stock that will function on a high-speed gum-wrapping machine.

For can-label stock, to which spirit varnish is to be applied, an entirely different formula is required. In the light of these conditions and many others the paper-manufacturing industry has a need for continuous and extensive research.

Due to the depletion of our national resources—and this applies particularly to our forests—it will be necessary to find a substitute for wood fiber. Recently great strides have been made in the utilization of sugar-cane refuse for paper making. This is being offered to the trade at the present time. Reforestation naturally will play an important part in prolonging our supply of wood. However, substitutes will be a necessary adjunct. In the lithographic field much is now being done to improve and simplify the process. At the present time experimenters are endeavoring to make a printing plate that will last indefinitely. The average life of a plate at the present time is about 50,000 impressions, and there have been instances where a plate has produced as high as 500,000 impressions. This proves that under the proper conditions plates can be made that will compete with electrotypes. The lithographic process is over a century old, nevertheless the facts related prove that we do not have a complete knowledge of the subject. There are tremendous opportunities in store for the research chemist.

Some inventors have endeavored to create a process of dry lithography, but at the present time have not met with great success. Possibly the nearest approach to the goal is the new Pantone process, recently brought out in England. It is claimed that a plate produced by this method will last indefinitely. The announcement of the electrodeposition of rubber on metallic surfaces attracted considerable attention, but up to the present time it has not been a commercial success as regards the lithographic industry; however, it has possibilities in connection with better printing surfaces. Further opportunities are seen in conjunction with the photo-litho process, and we look forward to the time when the offset press and photo-composing methods will remove many of the difficulties which exist at the present time.

The manufacturers of paints and varnishes have conducted many experiments and tests dealing with the oxidation of linseed oil, and much valuable information has been obtained on the subject. However, great possibilities exist to further this important work which is so vital to the paint manufacturer. The lithographer is particularly interested, and his problems in this respect are serious and of great importance. The use of different pigments in conjunction with linseed-oil varnish results in oxidation processes which vary considerably as regards the time element. In order to expedite matters it is necessary to employ catalysts, which accelerate the processes by providing more oxygen to the molecules. This variation in oxidizing qualities is a serious problem for the printer, and affords great opportunities for improvement.

### Some Recent Lithographic Reproductions

One commercial-art subject which attracted much attention was the Mazda calendar of 1927. This represented the application of fifteen colors and tints applied by the offset method, and the average layman can hardly realize how it would be possible to utilize so many. This reproduction, entitled "Reveries," presents a beautiful garden and a sparkling pool of water from which rises a fountain beneath which repose two female figures representing youth in all its charm.

To produce this picture in the proper color harmony it was necessary to employ a large number of colors and tints, possibly four different blue tints, as well as several pinks, browns, etc. The Mazda calendars for several years, including 1928, it may be said, have been lithographic masterpieces.

One lithographer has been very successful in reproducing oil paintings by the great masters which defy the most skilled artist to select the original from a distance. These reproductions are on sale in the art stores and retail for as much as ten to twelve dollars each. They require many tints to secure the proper tone and color value.

Some of our advertisements are art subjects of distinction; for example, the one depicting a girl in summer attire and youthful beauty, calling our attention to the merits of a popular beverage.

Sometimes it has been necessary to utilize as many as twenty-two colors and tints to produce an intricate subject. These are rare cases, however, and unusual.

In the superimposing of colors in the planographic process it is customary for can-label work to print the less opaque colors first and follow in sequence with the more opaque; the first colors are the yellows and greens, followed by the dark blues, reds, browns, blacks, etc., according to the subject to be produced.

Great care has to be exercised in timing the application of the several colors. If the first colors become thoroughly dry before the succeeding ones are printed they will not lift properly; also the second application will not oxidize properly because the first colors become hard and eliminate absorption, in which case the later colors are on the surface and require a much longer time to become dry.

### Some of the Processes Employed in the Lithographic Industry

*Collotype.* The planographic field comprises several processes which are in use today successfully, one of the earliest being the collotype process, invented by Louis Alphonse Poteoin, a French chemist, in 1855. In this process a film of gelatin is prepared in such a way that it can be printed lithographically by being made selective to greasy ink and water. The gelatin is first sensitized with ammonium bichromate and given a grain on drying. It is then exposed under an ordinary photographic negative, washed and dried, after which it is treated practically the same as a lithographic stone, having closely corresponding properties. Another process quite similar to the collotype is the aquetone.

*Photogravure.* Photogravure or intaglio is a process of printing from a copper-covered cylinder on which the image is etched below the surface by means of acid, the tints and shadows being controlled by the depth of the etching and the halftone dots.

The copper plate for photogravure is first prepared with resin dust. A positive transparency is made from a photographic negative and from this a print on carbon tissue, which latter is then pressed down on the prepared copper plate and developed; following development the plate is etched with perchloride of iron solutions of various strengths. The etching will be deepest in the shadows and least deep in the high lights. In printing a shiny coated paper is used and an ink of light consistency. Surplus ink is removed from the surface of the cylinder by a scraper, the remainder being applied to the paper in the usual manner.

*The Pantone Process.* One development which some authorities feel holds forth great promise is the Pantone process, recently bought out in England.

In this process a very smooth sheet of iron or mild steel is successively electroplated with an exceedingly thin coating of nickel, a coating of copper about 0.006 in. in thickness, and a thin coating of chromium. The plate is further coated with photoengravers' enamel, exposed under a halftone negative, developed, and burned in. This procedure is followed by etching in glycerin and hydrochloric acid which eats away only the chromium. After this the plate is placed in a silver or gold plating bath, where metal is deposited in the recesses formed by the etching process.

The enamel is then removed and the plate rubbed with a mixture of mercury and chalk to amalgamate the silver or gold areas. This provides areas of ink-receptive chromium forming the blacks of the image, and amalgamated areas of ink-rejecting gold or silver distributed over surfaces of the plate and forming the whites of the image.

By using an ink compounded with a certain amount of mercury it is possible to produce a satisfactory impression. The originator claims that there are great possibilities in this method as it produces plates which will last indefinitely.

In conclusion the author wishes to state that future developments will undoubtedly make it possible to secure a million or more impressions from a planographic plate, which will make it a competitor of the electrotype. And with such plates in combination with the modern high-speed offset press, the future offers great possibilities.

As I see it, the lithographic field is divided into two or more groups: One where mass production can be applied, this involving the production of three- and four-color labels of various kinds, seed packets, children's books, and work of that nature; the other a group where art subjects are printed in smaller quantities requiring greater craftmanship and skill. It would be very difficult to apply production methods to this class. In the former case, standardization of materials plays an important part and the control of materials used so far as uniformity is concerned. In mass production applied to the industry, uniformity is absolutely essential and scientific instruments will and can play an important part. This concerns the paper medium, inks, chemicals, gums and the many product which are used in the process.

## Discussion

J. R. Blaine.[2] The author's treatment is concise and suggests several points where material improvement and advance can be looked for. Fundamentally, lithograph printing is planographic printing and as such has problems quite different from letterpress or raised-surface printing. The main difference is found in the printing contact on the sheet. This contact is theoretically a line contact, but in practice is really a surface contact extending the entire width of the cylinder and depending upon the amount of yield in one or the other of the contacting members, be it cylinder packing as in direct lithography or rubber blanket as in the offset process. This contact pressure comes over the entire sheet during the revolution of the cylinder no matter where or what the size of the design may be. It brings in to a much more vital degree the question of how the stock "lays." For this reason wrinkles, distorted sheets, and misregister are more common than in letterpress printing. These troubles can be minimized, as is done in some of the larger establishments where air-conditioning apparatus is installed, which keeps the temperature and relative humidity under constant control, in the pressroom as well as in the seasoning room.

Another problem in lithography which demands attention is the question of water. No doubt the greater percentage of printing trouble is directly traceable to the fact that water is as necessary as ink. That this is realized is shown by the attempts now being made to eliminate the water entirely by substituting an ink-repellent surface such as described by the author in the paragraph headed "Pantone process." So far, it can hardly be considered a success, as it is still in the experimental stage. Other experiments on extending the life of lithograph plates are being tried, and no doubt will lead to improvements which will increase the number of impressions many times over what is now possible.

This is the age of mass production, and nearly all industries, including the printing industries, are profiting by the experience of the automotive organizations. Modern presses are built for speed, and improvements are made to increase running or producing time. This is as it should be. However, the writer has felt that there is a lack of cooperation or rather of understanding between the artists, designers, and advertising men in that greater production, better quality, and consequently lower cost

[2] Mechanical Engineer, Miehle Printing Press and Mfg. Co., Chicago, Ill. Mem. A.S.M.E.

could be obtained if they were to study their designs and compositions in the light of just what the press must do in reproducing the subject. We all know that artists are temperamental, and perhaps that is the reason no one dares "take the bull by the horns," as it were, and tell them what to do. However, the advertising manager cannot hide behind this excuse, and it would seem that help might be expected from this end. It would be interesting indeed to know just how much running time is lost in a year due to the fact that the artist or advertising manager insists on some insignificant point or combination as regards color or register composition.

Winfield S. Huson.[3] The fullness of the author's paper invites discussion from several angles. It is in the closing paragraph, however, that the writer feels he detects an accentuation of a vista of the future on which the paragraph touches. It may seem idle speculation to dwell on the great possibilities spoken of; nevertheless, the tenor of the paper points to advancement and marked change in present method and practice.

To those who closely follow printing in its intricacies, every thought that conduces to application of new discovery and skilled investigation, particularly in the field of chemistry, senses itself in the broader thought that printing, as we know it today, must ultimately be produced through the results of laboratory research.

It may be, too, that these remarks seem irrelevant to the usual discussion that might be expected on so excellent a paper, but when one knows the circuitous ways of present practice in the preparation and production of printed matter, as pointed out, and then considers what has and is being done by photography—for instance, the recent demonstration of direct-color reproduction, also the chemical reactions as outlined in the paragraph on the Pantone process as showing satisfactory response to positive and negative attraction—and other research, it lends conviction to the view that planographic or surface printing is an able forerunner of the coming event.

The printed page will be produced from a plane surface on which the magic of light has been impressed in all the beauty of the chromatic spectrum, which as it is imparted to the printed sheet will be continuously built up by the response of selective chemical affinities to color tones.

How it will be done, the laboratory will find out. So do not be surprised if some day our literature comes to us in all the resplendence of color sensation, and the production raised to a bewildering quantity, all in one running through the press—if it is still called by that name.

The outlook may not be encouraging to the ink and the plate maker, but their work will not be lost in the scheme of things as we delve in nature's laboratory to uncover the elements and factors that will contribute to further high achievement in the everlasting art of printing.

[3] New York, N. Y.; Chairman, Progress Report Committee, Printing Industries Division. Mem. A.S.M.E.

Randolph T. Ode.[4] I would ask the author if, with air-control in the summer, does he still have trouble with the paper?

Mr. Van Vechten. According to the best authorities on the subject, we should not have any trouble if we maintain an average temperature or a moisture condition of the atmosphere throughout the year. In our experience, when the outside conditions are extreme, even when we have the inside conditions under control, the paper is affected to a certain extent.

Mr. A. J. Newton.[5] Is the inside entirely under control?

Mr. Van Vechten. So far as we can tell.

Mr. Ode. Have you found that it will help you materially in the summer time?

Mr. Van Vechten. Quite materially; it eliminates a number of days in the summer time when it is necessary to shut down due to very humid conditions.

Mr. Ode. Would you find any improvement in five-color operations when the job is begun and ended on the same operation?

Mr. Van Vechten. I think that is quite an improvement.

Walter E. Sooy.[6] Speaking of relative humidity, what percentage of humidity do you recommend for the air in the pressroom? Would you have trouble with static electricity if the proper relative humidity is maintained?

Mr. Van Vechten. We find that it does not when we carry a relative humidity above 45 per cent or somewhere in that neighborhood.

Mr. Ode. What have you found to be the correct humidity to use?

Mr. Van Vechten. We feel that the correct humidity is a point that never has been definitely determined. According to to the experience of other lithographers as well as ourselves we have selected a humidity that is in the line of economics and which can be maintained with the lowest possible cost.

Mr. Ode. You said something about 45 per cent.

Mr. Van Vechten. I said that the lithographer, the practical lithographer, preferred a low humidity.

Harold E. Vehslage.[7] Is that apt to vary from season to season, from winter to summer?

Mr. Van Vechten. Do you mean if we do not have control?

Mr. Vehslage. No; would you find the relative humidity should be higher in summer or in winter?

Mr. Van Vechten. It is better to maintain an average humidity throughout the year. That is why we selected 45 per cent as the most economical point to maintain.

# Progress in Railroad Mechanical Engineering

## Contributed by the Railroad Division

Executive Committee: H. B. Oatley, *Chairman*, Marion B. Richardson, *Secretary*, William Elmer, A. F. Steubing, R. S. McConnell, and Elliott Sumner

As 1927 is the centenary of various railroad systems in this country, the recent and most elaborate celebration being that of the Baltimore & Ohio Railroad, it may not be out of place in this year's report to include a few figures which will briefly indicate the colossal proportions to which the American railway system has grown during the past 100 years.

The total investment in Class I roads now amounts to more than 24 billions of dollars; their mileage is in excess of 250,000, representing more than one-third of the world's total. On January 1, 1927, these roads operated 62,800 steam locomotives, which had an aggregate tractive power of 1,304,000 tons. As of the same date, these roads operated 2,350,000 freight cars which had a total carrying capacity of 105,717,000 tons. Over 1,000,000 cars were loaded each week during the year, and they carried 3791 tons of freight one mile for each inhabitant of this country. These figures give a background for an appreciation of the important place, in the economics of this country, which is occupied by our basic transportation industry. Lack of progress in development, and particularly in all of the engineering problems involved, would be a deterrent in the business and economic life of our nation. Such depressing effect, while it cannot be evaluated, would be admittedly enormous. A record of the progress which railway mechanical engineering has made, therefore, is always of value, and as the centenary of railroad beginnings is occurring, it becomes of more than ordinary interest.

During the past year the progress in railway mechanical engineering has been steadily toward bettering the operating efficiency of railroads by continuing the effort to increase the gross ton-miles per freight-train-hour. This unit is becoming generally recognized as a most valuable index. Part of the accomplishment is due to heavier and more efficient motive power, part to improvements in signaling, heavier car loading, etc.

"Railroad efficiency is a factor of national prosperity" has been a motto always in the mind of progressive railroad men. Efficiency in the purchasing and maintenance of stock material suitable for the requirements, but not involving an unnecessary investment, is an activity which, during the past year, has made marked progress. Intensive effort to avoid excessive surplus material has been made.

That some, at least, of the views expressed in previous reports of this committee have been brought into reality may be evidenced from the following quotation of a leading railroad executive:

> From the mechanical viewpoint, the most significant developments in the railway field are the design and construction of high-pressure steam locomotives, of oil-electric locomotives, and of very high-capacity electric locomotives; the application and operation of capacity- and efficiency-increasing devices to what may be called the normal type of steam locomotives, and the design and construction of locomotives of this same normal type so that they show more reliability in service, more economy in operation, and have a lower annual repair cost and a longer life.

The campaign for greater economy in the use of fuel, in which the International Railway Fuel Association and the Traveling Engineers' Association have been factors of great importance, has made progress during the present year.

The average daily movement per freight car for the first seven months of 1927 was 29.8 miles, the highest mark ever attained in any corresponding period, according to reports filed with the Bureau of Railway Economics. This was an increase of one-half mile above the best previous average established in the first seven months of 1926.

The campaign for greater safety, while not a mechanical-engineering problem, is of such intense human interest that endorsement of these efforts is not out of place in this report, and such endorsement is heartily given.

Progress in standardization of weighing equipment complying with the requirements of the American Railway Engineering Association and of the Bureau of Standards, has been reported as having made marked advancement during the current year.

### Motive Power

The tendency toward higher steam pressures in locomotive boilers is going forward, the Delaware & Hudson Company having put in service its 400-lb. *John B. Jervis*, and the Pennsylvania is engaged in designing a 2–10–0 type with 450 lb. pressure. Auxiliaries are operated with superheated steam; enlarged grate areas, and greater firebox volumes are being used in increasing numbers, as are also feedwater heaters and exhaust-steam injectors. Three-cylinder locomotives are being bought in considerable numbers.

Experiments are still being conducted with oil-electric locomotives in switching service. The Chicago & Northwestern have added storage batteries in order to reduce the weight of the primary power plant.

The effort toward long locomotive runs is continuing, and in this effort larger tenders and a better spacing of water stations are proving effective.

Cast-steel underframes for tenders are being more extensively used, and experiments are being conducted with one-piece cast-steel locomotive frames and, on one road, with a cast-steel smokebox.

There is increased activity in and development of a modified boiler construction permitting more satisfactory service, not only for use with higher steam pressures, but with consideration of better water circulation and the reduction of corrosion effects. Consideration is also being actively given to the proper adaptation of condensing operation as well as to the use of air preheaters.

Reference to Table 1 shows the marked increase in the use of four-wheel trailing trucks on locomotives. It is to be noted also that practically all of the new and advanced designs of locomotives constructed during the year have had this feature, and also that a large proportion of the new designs have been built for steam pressures ranging between 220 and 300 lb. per sq. in. The tendency in this particular, mentioned in previous reports, has been progressing during the current year. A number of the new designs of locomotives have made use of nickel, or silicon, alloy steel for the shell plates of these higher-pressure boilers. Reports of the service of this material have not shown any indications of difficulties, and the advantages in reduced weight for a given set of conditions appear to have been realized.

Indications, from the records covering the first half of 1927, encourage the belief that the fuel savings on locomotives will

TABLE 1 DATA ON NEW DESIGNS OF LOCOMOTIVES

| Road | Type of engine | Boiler pressure lb. | Cylinders No. | Cylinders Max. hp. | Type of superheater | Back-pressure gage | Feed-water heater or injector | Max. cut-off, per cent | Throttling between super-heater and steam chest | Grate area, sq. ft. Total | Grate area, sq. ft. Per 100 hp. | Remarks |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

| So. Ry. of Eng. | 4-6-0 | 220 | 4 | — | — | — | Inj. | — | — | 33.0 | — | ...... |

amount to approximately $17,000,000 as compared with the year 1926. The consumption per 1000 gross ton-miles in freight service for the first four months of this year was less than for the corresponding period during the year 1926. If this rate of reduction is maintained, the 1927 figure will be 129 lb.

### Rolling Stock

Experiments are being made with lacquers for both the exterior and interior finish of coaches and dining cars.

A number of railroads are putting motor buses on the highways as feeders to, as well as paralleling, their steam routes. Larger and higher-powered motor rail cars have been developed to haul one or two trailers.

The rapid advance in the use of self-propelled cars is evidenced by the fact that over 200 of such units were purchased during the first half of the year 1927.

The American Railway Association standard box car has been designed, and plans are being prepared for hopper and gondola cars. One road is experimenting with a solid cast-steel underframe for freight cars. Improvements in refrigerator cars involve trials of the "silica gel" process and "dry ice" or solid $CO_2$.

Automobile cars of new design, embodying side doors 12 ft. in width, have been built by the Chicago, Milwaukee & St. Paul, the Missouri, Kansas & Texas, and other roads, to meet an urgent demand from automobile manufacturers for cars with wide side doors, so that easier loading of completed automobiles is afforded. Reference should be made also to the 70-ton hopper gondola cars put in operation during the past year by the Delaware, Lackawanna & Western Railroad.

### Economics

From the economic standpoint, we have the benefits realized by shippers and merchants because of the rapid and reliable movement of freight and passenger traffic; the rapidly increasing safety of travel, and especially the steadily decreasing net income of the carriers, which follows the many reductions in freight rates on the one hand and the alarmingly rapid increase in taxes and in payments to railroad workers on the other.

It is gratifying to note a change in public sentiment toward corporate interests, and particularly toward the railroads. A more sympathetic and appreciative viewpoint on the part of the public toward the progressive efforts of the railroads cannot help but have a beneficial effect upon all interested parties.

Greater efforts toward informing the general public of the engineering and operating progress is proving a wise move, and the railroad industry in general is to be commended for its efforts in this direction.

From the political standpoint, we have the growing political power of the standard labor unions; the desire of many politicians to stimulate railroad consolidation and to reduce freight rates, without regard to the cost of the service; and the thinly veiled designs of many to work toward Government ownership of the railways.

The increase in efficiency and reliability of the railroads, since 1920, has affected the every-day life of every individual. There have been no strikingly important changes in the machinery or processes during that period, although large sums of capital have been invested in the direction of modernizing and increasing the capacity of the railway plant.

Progress in extending the use of automatic train control, improved automatic signal systems, and more efficient operation in freight classification yards is also to be recorded for the year.

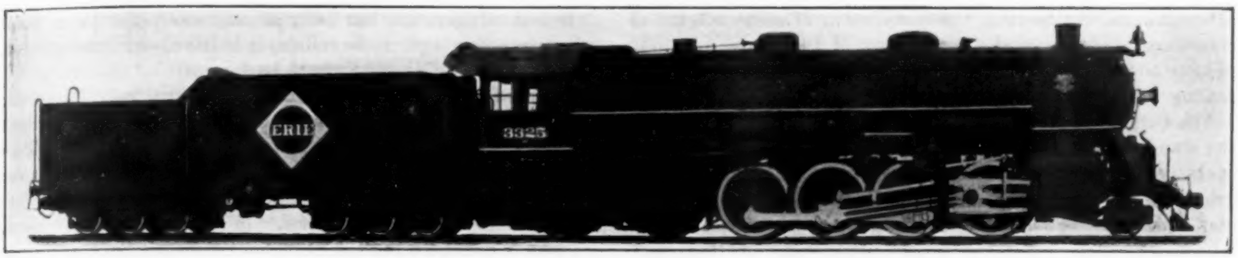
### Technical Training

Questionnaires were sent to all the technical schools and colleges that maintain courses designed to prepare students for railway-mechanical-engineering work. The replies show that the various educational institutions are beginning to feel the results of a greater effort on the part of the railroads and railway-supply companies to cooperate in the training of men for their respective industries. In addition, the American Railway Association has been utilizing the laboratory and test facilities afforded by the various educational institutions, especially at Purdue University.

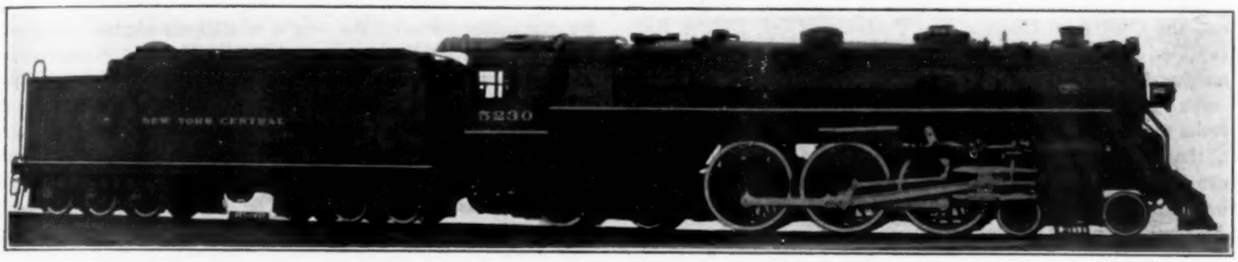
The Pennsylvania State College has for some time been studying the problem of insulation and heat transmission, factors in the efficient insulation and cooling of refrigerator cars and the heating of passenger cars. Considerable progress in this work has been made in the past year.

A number of radical changes are being considered in the courses of study offered to students in railway mechanical engineering. For a number of years past different institutions have maintained courses in their curricula leading to the degree of Bachelor of Science in railway mechanical engineering. Among the most prominent have been the University of Illinois, Purdue University, Pittsburgh University, and The Pennsylvania State College. Some of these institutions abandoned the course a number of years ago and combined the railway course with the straight course in mechanical engineering, along much the same lines as the average course of study in civil engineering. Pittsburgh University, it is understood, and the Pennsylvania State College are, however, still maintaining a course in railway mechanical engineering. The latter institution, however, is seriously considering the abandonment of this course and including the more important railway subjects in its mechanical-engineering course.

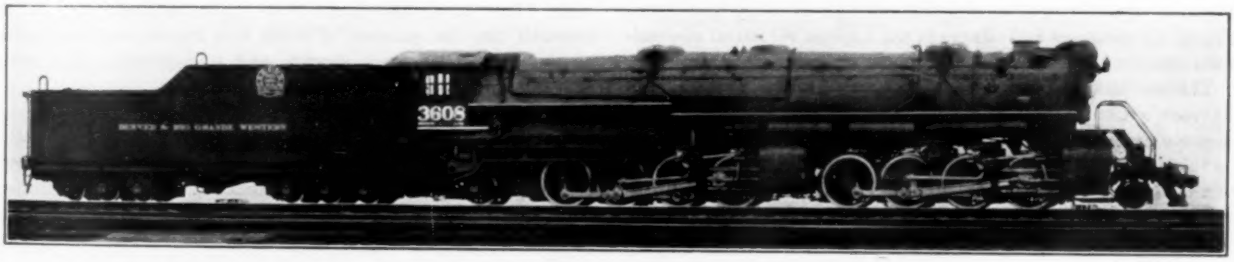
In many respects this trend in railway-mechanical-engineering education will be beneficial from the standpoint of both the railroad and railway-supply industries. It is generally felt that mechanical engineers should have as broad an education as possible, and that specialization in college is not beneficial. It is also felt that a considerable improvement can yet be had in the educational field by a more careful selection of students



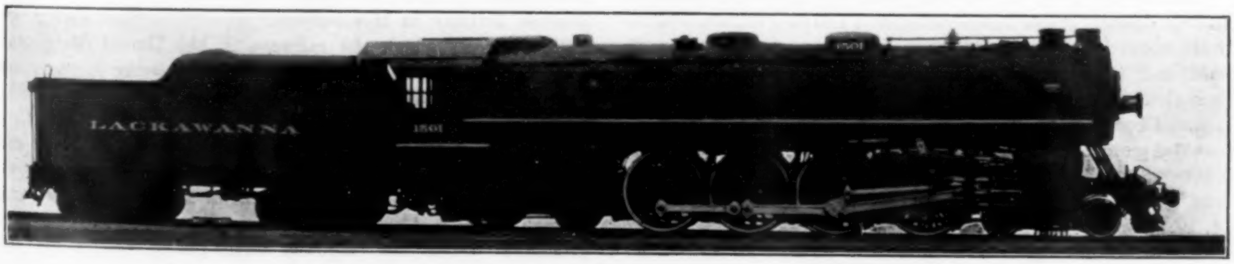
2-8-4 Locomotive Built for the Erie, and Equipped with Booster



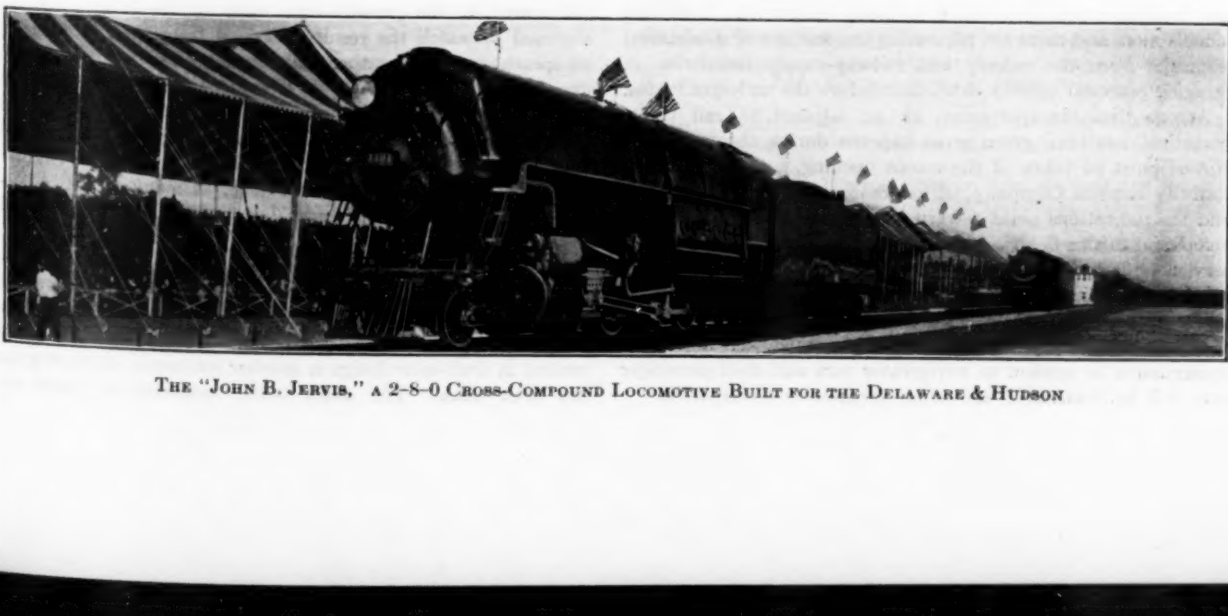
New York Central Locomotive of the Hudson Type (4-6-4)



2-8-8-2 Locomotive Built for the Denver & Rio Grande Western



4-8-4 Locomotive Built for the Delaware, Lackawanna & Western



The "John B. Jervis," a 2-8-0 Cross-Compound Locomotive Built for the Delaware & Hudson

in mechanical engineering, the installation of some scheme of vocational guidance, and the planning of the course of study to more adequately serve the mechanical engineer in railroad work dealing with steam turbines, gas engines, electric traction, etc.

The outstanding development in this field of education, from the standpoint of the railroad and railway industries, is the cooperative plan in engineering and commerce instituted several years ago by the Georgia School of Technology. The original plan of cooperative education for engineers was first instituted in September, 1920, when the textile department of that institution arranged a course, to cooperate with the cotton mills, in the education of textile engineers. Since that time the cooperative plan has been extended to a number of railroads; viz., the Central of Georgia, the Tennessee Coal, Iron & Railway Co., the Georgia Railway & Power Co., the Atlanta, Birmingham & Coast, and the Nashville, Chattanooga & St. Louis. Under the cooperative plan the student spends alternately four weeks in college and four weeks in mechanical-engineering work in the railroad shops at Atlanta, Ga., and the cities within a radius of about 300 miles. By this arrangement the Georgia School of Technology has available two courses in mechanical engineering: viz., the standard four-year theoretical course as given by other engineering colleges, and a five-year course for those students who wish to combine practical experience with technical theory. The cooperative course is under the administration of a director, an assistant, and an advisory board consisting of executives and officers of the various industrial and railroad companies with which the school cooperates.

The research work that is being carried on by the Railroad Division's Committee on Professional Service shows that the opportunities afforded in the railroad industry are comparable to those afforded in any other industry. In all probability there will be a larger number of mechanical engineers entering railroad work in the future. It is believed that an institution offering courses in mechanical engineering could offer a better-balanced course if the design and operation of motive power and rolling stock were included in the mechanical-engineering curriculum.

Considerable progress has been made by the Sub-Committee on Professional Service in collecting facts and information relative to the opportunities afforded the mechanical engineer in the railroad and railway-supply industries. A progress report was presented at the annual meeting in December, 1926, which included considerable data collected up to that time. That report was published in full in February, 1927, issue of MECHANICAL ENGINEERING. A second report will be presented at the Student Branch Meeting of the Metropolitan Section on March 14, 1928.

### Trend in Development

Closer cooperation between technical schools, the railroads, and railway-supply companies is being evidenced. Technical schools more and more are requesting the services of mechanical engineers from the railway and railway-supply industries in bringing practical outside viewpoints before the undergraduates.

Aeronautical transportation, as an adjunct to rail transportation, has been given great impetus during the past year. Notice must be taken of the recent opening, by the American Railway Express Company, of its transcontinental air service, and the indications point toward an even more pronounced development in this field. Aerial transport coordinated with train service under railway-company operation, as well as by independent companies, may confidently be looked for within a relatively short time.

Research and development work in insulation and heat transmission as applied to refrigerator cars and steel passenger cars will be continued, and rapid progress is anticipated.

Iceless refrigeration has been already developed to a point where its advantages in the railway field have been demonstrated, and its extensive use appears to be forecast.

Motor-truck and bus service has been extended. Particular attention is being given to determining conditions under which further extension, from the standpoint of economy and advantageous coordination with steam service, may be made. Mention must also be made of the increase in "auto-bus tours" as an adjunct to passenger travel. In this field the Atchison, Topeka & Santa Fe and the Southern Pacific are the best known. The indications are that there will be considerable increase in such auxiliary services.

The development of the Diesel-electric power units, suitable for rail motor cars, with a weight of engine and generator of not over 26 lb. per hp. has been brought to the Committee's attention. Light-weight units of this character and of a size and flexibility suitable for rail-motor-car use offer encouragement to the further adaptation of this equipment in the not-far-distant future.

Diesel-electric locomotives, arranged for multiple-unit control and suitable for road service, are under construction for the New York Central Railroad. The Ingersoll-Rand Company, the McIntosh & Seymour Corporation, and the General Electric Company are developing and perfecting this method of control.

The American Railway Association's draft-gear tests at Purdue University were started with encouraging results during the year. The same association has made progress also in its research into the question of truck side frames, and the results of this important work should, and undoubtedly will, prove of great benefit to the railroad industry.

Some attention has also been given toward applying mechanical draft to locomotives by using turbine-driven fans for forcing air below the grates. The question of the use of pulverized fuel also has received further attention. Definite reports as to the amount of progress which has been made along these lines have not been available.

Efficiency in the use of fuel, particularly as affecting the smoke-abatement problem, has been actively pursued and considerable progress reported. St. Louis is the center of the greatest activity in this subject.

The interest which the railways in the United States and Canada have in the application of roller-bearing journals has shown a marked increase within the last 12 or 14 months, particularly since the American Railway Association's Atlantic City Convention of June, 1926, at which time exhibits of trucks and other equipment thus fitted attracted no small amount of attention. Prior to this time several railways had been operating a small number of test cars. Within the last 18 months, four prominent trunk-line railroads have placed orders for 480 roller-bearing-equipped passenger cars of all types, all of which are now in service. The largest single order yet placed was for 133 cars. At the present time most of the other roads are disposed to watch the results obtained from the roller-bearing equipment in service rather than to proceed with any wholesale experimenting themselves. It is evident, however, that within the next year or two the manufacturers and the railroads will be possessed of useful data on the operating conditions of this type of bearing, as well as upon the relative merits of competitive types. Particularly is the latter true, as many of the operating advantages have already been well defined by actual tests.

The increase in size of motive power, the length of trains and the larger-capacity cars now in use have brought about modification and improvement in draft gears which provide for the more severe service conditions. The problem of slack control in draft-gear design is another subject in which progress has been made. The much better condition in which air-

brake apparatus is now maintained by the railroads is to be noted. Research in the air-brake field has been continuous and has resulted in the bringing out of a new type of feed valve having greater stability, reliability, and capacity, and a reduced cost in operation and maintenance. There have also been developments in brake-cylinder pressure-retaining valves and in the methods for more uniform application and release of brakes in passenger trains. The increasing use of higher steam pressures and higher steam temperatures has influenced development in air compressors and governors.

The increasing length of passenger trains has been appreciated by the manufacturers of train-heating equipment, and the past year has seen the application of train-heating equipment giving greater assurance that the rear cars of these long trains would be adequately heated. In this development, progress has been made in adapting modifications to the requirements of interchangeability between cars thus equipped and others.

The probable trend of development in the railway field within the next few years will be in the direction of enabling the railways to obtain a greater net income than has been the case during the last ten years. This increase in net income is necessary if the railway plant is to be enlarged so that it may, promptly and effectively, perform the work which it will be called upon to do, and, also to enable it to operate at a cost that its patrons can afford to pay.

### Bibliography

The appended bibliography, while not complete, is nevertheless believed to contain references to published information on most of the subjects covered in the Committee's report. It contains references to articles that have been suggested to the Committee by the various railroads and representatives of other industries which have favored the Committee with information, and appreciation of this cooperation is hereby acknowledged.

H. B. Oatley, *Chairman*.

# The Mechanical Engineer in the Railroad and Railroad-Supply Industries

IT IS THE belief of the Railroad Division's Sub-Committee on Professional Service that the opportunities afforded the mechanical engineer in the railroad and railroad-supply industries are equal to those afforded in any industry. This belief is based on several facts which are later discussed in this report, probably the most significant of which is that competition with other college-trained men is not as great as is the case in many other industries. A study of the careers of 150 railway officers holding positions from president down to master mechanic, shows that only 43.7 per cent are college graduates. The railroad-supply industry, however, presents a slightly different ratio, 63.6 per cent being college graduates out of a total of 113 railway-supply-company officers ranging from president down to sales representative. In both cases the officers were selected at random with the primary object of obtaining as accurate a picture as possible of the competition to be expected by the mechanical engineer in both industries.

These figures are also significant of one other important factor pertaining to the success of the individual in railroad and railroad-supply work. Knowledge of railroading, individual adaptability, practical experience, and a willingness to work appear to have considerably more value in the mind of the average executive than college education.

It is not the general practice of the railroads to extend preferential consideration to college graduates. It is expected that the college graduate will start on an equal footing with the non-college man and show his worth in actual service. In other words, the college man is worth comparatively little to a railroad company until he has had considerable practical training and experience. This, in the main, is also true of most industries employing technical graduates.

This situation is well described by Robert E. Woodruff in the foreword of his book "The Making of a Railroad Officer."[1]

> To most men, railroad history and stories are fascinating because they are filled with action and achievement. Lives of railroad men are romantic, treating as they do of the hardships of their rough outdoor life. Railroad men are as a whole active, resourceful, enthusiastic. They play the game because they love it. Thousands enter the service each year. Some cannot stand the pace and seek easier jobs in other lines. All begin at the bottom in some capacity or other—there is no royal road to the top.
>
> Some advance, some slowly, but surely—others stagnate and are sidetracked. When questioned, most men are ambitious for achievement, though many are ignorant of how to accomplish it or of where to get the necessary knowledge. Some do not realize they must fit themselves for larger responsibilities before they can be seriously considered for promotion.

Incidentally, Mr. Woodruff starts his future railroad officer as a section laborer.

### How to Use the Information Contained in This Report

Much of the information contained in this report was obtained by studying and analyzing the careers of railroad and railroad-supply officers, published in the railway trade press. This was also supplemented by writing direct to the various companies for additional information. The Sub-Committee on Professional Service has assumed from the beginning of its work on this project that what the young mechanical engineer wants and should have are facts, not advice. He ought to have a fairly accurate picture of the industry he expects to work in before he enters it. Such a picture is not difficult to obtain if one takes the time to assemble and study the facts. A study of the careers of railroad and railroad-supply officers has been made in preparing this report, and it will reveal many essential facts. Additional information can also be obtained from those who are now engaged in railroad and railroad-supply work.

Facts obtained from the last source mentioned should, however, be given careful consideration. To have won success in one's chosen profession does not always qualify one to fill the role of adviser in the selection of another's life work. He may, in fact, be disqualified by that very circumstance. On the other hand, a man who has spent the best years of his life near the bottom of the ladder is likely to paint a pessimistic picture of the opportunities to be found in railroad work. Still, a good business man makes his banker his friend and counselor. Likewise, the young railroad man should make it his business to cultivate friends and advisers among the older railway officers.[2]

Study of the facts and information contained in this report should be supplemented by consultation with railroad and railway-supply-company officers, and with members of the mechanical-engineering faculty of the institution the student is attending. The burden, however, of making the final decision should rest with the young mechanical engineer himself.

It must also be appreciated that opportunity in a certain industry is very closely allied to the progress that is being made in the way of developments within the field itself. The young mechanical engineer should study the report of the Sub-Committee on Professional Service in conjunction with the report of progress in the industry which is presented by the Railroad Division each year at the Annual Meeting of the Society. Also, the *Railway Age* publishes a special issue, the first number of the year, known as the Annual Statistical Number, which contains a comprehensive review of developments and accomplishments in the industry during the preceding year.

### Question of Knowing One's Own Ability

It is essential that the young mechanical engineer know his own characteristics and ability. In finding these out, he can obtain considerable assistance from his friends and faculty advisers. The graduate from an engineering school who anticipates a railroad career should carefully consider two questions, namely, "Do I want to use my engineering education as a basis for a purely engineering career, or do I want to use it, together with a supplementary business education, as a means of eventually reaching an executive position?"[3]

The man who would follow the first course and who is interested in engineering work for the work itself, or in new design and construction, is sure to suffer somewhat of a disappointment in railroad service. Unfortunately, relatively little of the work

[1] "The Making of a Railroad Officer," by Robert E. Woodruff, General Manager, Eastern District, Erie R.R. Published by the Simmons-Boardman Publishing Company, New York.

[2] See "What Opportunities Are Afforded the Technical Graduate in Railroad Work," by Marion B. Richardson, beginning on page 13 of the March, 1926, issue of *The Penn State Engineer*.

[3] See the *Railway Age*, June 12, 1926.

performed by the average railroad mechanical-engineering office is of a nature that will keep a talented designing engineer continuously occupied with new and interesting problems. The development of the railroad-supply industry has had an important effect in placing the larger part of the design work in the mechanical-engineering department of the manufacturer. In all probability the man following the first course will find greater opportunity in the supply industry.

If the college man entering railroad service is the type who wishes to use his engineering education as a means of possibly reaching an executive position, either in or above the engineering department, then there is one thing that cannot be overlooked—as he advances he gradually becomes more of a business man and less of an engineer. If he has failed to educate himself in the principles of business, the chances for becoming an executive are not great. The railroad executive whose duties may demand an engineering knowledge are such that a relatively small portion of the things which he must know involve a detailed knowledge of engineering principles as compared with the principles of business administration.

The mechanical department of a railroad is but a part of an immense business organization which, like any other business, is operated to make money. Unfortunately, the mechanical department is in a position principally to spend money and save money; as a consequence, the labors of the members of that department are often looked upon as "non-productive." If a college man intends to enter railroad service and be satisfied with what he can learn in any one office or department, he will make no greater progress on the railroad than if he pursued the same tactics in any other industrial organization. The big thing is to know enough about the job ahead to be able to step into it when the opportunity offers, and this calls for self-education in the principles of business.

Unfortunately, a railroad cannot be run on paper. Operations may be carefully planned beforehand, but conditions over which no one has any control may make it necessary to alter these plans at the last moment. Therefore, any college man in railroad service who fails to get as much as possible of the practical side of railroading is doomed to make little progress in railroad work. Any man who has spent four years in college learning how to think for himself certainly should not be at a loss for ways and means to get all he wants on a railroad.

The Railroad Division's Sub-Committee on Professional Service does not believe that to confer a distinctive title upon a college man in railroad service would materially better his situation. In fact, some consider such titles a considerable handicap. "Titles can be created with the flourish of a pen and wiped out with a bad breakfast." Some of the real jobs on any railroad are those which carry unimposing titles, and, on the other hand, some jobs with magnificent titles leave much to be desired on pay day. Every man who has had practical railroad experience realizes that it is desirable to emphasize his education as little as possible. What the young mechanical engineer should do, in railroad work or elsewhere, is to lose his identity as a college man as quickly as possible.

## Two Reasons Why Advancement Is Apt to Be Slow

There are two principal reasons why advancement in railroad work may be slow. First, because the business as a whole is so complicated and departmentalized that it takes years of actual work to become acquainted, even in a general way, with many phases of it. This is in contrast with any line of business that consists mostly of one or two operations, such as buying and selling, or the manufacture and sale of a limited variety of articles, the whole plant being in one place. In any such line, one with reasonable aptitude and liking for the work can much more quickly master its details and be in position to advance more rapidly than would be likely in a more complicated and departmentalized business.

The second reason is that the railroads have long since come to a stage of routine as contrasted with immediate and rapid growth. They are organized to handle their business from day to day, but are not expanding in any such manner as to call for a steady and large supply of trained men to fill newly created responsible positions. A man who may be very capable is apt to find himself in a situation similar to a bucket in a bucket brigade: that is, he passes along just as fast as those who happen to be ahead of him travel. This is an unavoidable condition in any organization that has attained its growth.

The second reason, however, is subject to a number of modifications. The railroad industry has been going through a number of important developments in recent years with respect to its employees that cannot help but effect an improvement in the status of the mechanical-engineering graduate. Many railroad companies are utilizing the facilities afforded by various state university-extension departments, vocational educational bureaus, correspondence schools, and other educational organizations for the training of foremen and supervisors. The requirements for the enrolment of regular apprentices are becoming more strict. Some railroads are now requiring a high-school education or the equivalent before a man can enroll as a regular apprentice. Many of the larger railroads are sponsoring such activities as the American Railway Boys' Clubs, the educational features of the Railroad Y.M.C.A., Younger Railroad Men's Conferences, etc., in an effort to raise the standards of supervision. Of course, this means more competition for the college graduate. But it also means more adequate appreciation and utilization of college training by the railroad executives.[4]

## Comparison of the Railroad with Other Industries

There are approximately 1000 railroads in the United States and Canada, about 176 of which are Class I railroads (railroads having an operating income above $1,000,000). The Class I railroads operate approximately 90 per cent of the total railway mileage in the United States and earn about 96 per cent of the total revenues. According to the November, 1927, Monthly Labor Review, published by the U. S. Bureau of Labor Statistics, there were employed on these roads in August, 1927, a total of 1,796,194 men and women. A comparison of this figure with the number employed by other industries during the same period is given in Table 1. The second largest industry, according to the number employed, is the iron and steel industry, the textile industry being third.

TABLE 1 COMPARISON OF EMPLOYMENT IN 13 GENERAL GROUPS OF INDUSTRIES DURING AUGUST, 1927

| | Number of establishments | Average number of wage earners |
|---|---|---|
| Railroads | Total Class I* | 1,796,194 |
| Iron and steel and their products | 1806 | 648,701 |
| Textiles and their products | 1885 | 602,623 |
| Vehicles for land transportation | 1194 | 479,826 |
| Car building and repairing, steam railroads | 559 | 138,381 |
| Miscellaneous industries | 413 | 251,850 |
| Food and kindred products | 1656 | 223,457 |
| Lumber and its products | 1156 | 219,669 |
| Paper and printing | 910 | 172,365 |
| Leather and its products | 360 | 128,564 |
| Stone, clay, and glass products | 638 | 109,776 |
| Chemicals and allied products | 362 | 88,679 |
| Metal and metal products, other than iron and steel | 228 | 51,595 |
| Tobacco products | 173 | 39,670 |

* Includes 172 Class I railroads, 15 switching and terminal roads of this class and 24 small roads included in system reports.

[4] Personnel Management on the Railroads, A Study by the Metropolitan Life Insurance Company. Published by the Simmons-Boardman Publishing Company, New York.

Figures showing the proportion of technical graduates—for our purposes, mechanical engineers—to the total number employed would be of value in this table. The Sub-Committee has not, however, found any source from which such information could be obtained. A general idea of the number of supervisory positions in which mechanical-engineering training would be of service is shown in Table 2. Care should be shown, however, in the use of the total figure, due to the fact that many of the executive and staff officers fill positions requiring legal, medical, or business training. Furthermore, this total does not include special apprentices. The division officers and assistants include men in all departments. The larger proportion of the architectural and engineering assistants are in all probability men of civil- or mechanical-engineering training. Special apprentices are usually made inspectors upon completion of their course.

TABLE 2 NUMBER OF EMPLOYEES HOLDING POSITIONS WHERE MECHANICAL ENGINEERING TRAINING WOULD BE OF SERVICE, AUGUST, 1927, ON CLASS I RAILROADS IN THE UNITED STATES*

| | |
|---|---|
| Executive, general officers and assistants | 7,551 |
| Division officers, assistants and staff assistants | 9,503 |
| Architectural, chemical and engineering assistants | 7,685 |
| Sub-professional engineering and laboratory assistants | 4,232 |
| General foremen, M. of E. | 1,440 |
| Assistant general foremen and department foremen, M. of E. | 11,129 |
| Equipment, shop and electrical inspectors | 1,585 |
| Material and supplies inspectors | 1,913 |
| Gang foremen and gang leaders, M. of E. | 11,036 |
| | 56,074 |

* Wage statistics report, Interstate Commerce Commission, for August, 1927.

A comparison of the total number employed with the total number of officers shows quite clearly that the principal job of the majority of mechanical-department officers pertains more to handling and leading men than to strictly mechanical-engineering work. To illustrate, the superintendent of the car department of one of the smaller Class I railroads in the East has an average of 1200 men under his jurisdiction working at different points on the system. As a further illustration, there are employed by the railroads in the maintenance of equipment about 484,000 men. As a comparison, there are about 1400 general foremen and 11,000 assistant general foremen and department foremen employed by the Class I railroads in the mechanical department. The general foremen are therefore captains of an immense army. Their work may be roughly divided into two parts: first, that of contributing to improvements in shops, shop methods, and shop machinery, and secondly, that of supervising and training employees and improving their morale.

This, in brief, is a summary of the experience and training the college graduate must have to fill higher positions. Finally, the young mechanical engineer must know and appreciate the fact that the railroad industry is subject to regulation by the Government.[5] As a rule, government agencies are slow to move and are likely to hinder the development of an industry unless they are able to keep in step with the times. The rules and regulations laid down by the Interstate Commerce Commission affect the work of all departments of a railroad, and it is necessary that the railroad officer know just how these regulations relate to the work of his department.[6] The railway-supply-company officer must also be sufficiently familiar with the rules and regulations of the Interstate Commerce Commission to meet its requirements in the materials that his company manufactures. Government regulation, however, has its good features as well as its bad, and fortunately the policy of the various bureaus of the Interstate Commerce Commission is one of helpfulness rather than hindrance. In addition, the American Railway Association, of which practically all the railroads are members, makes certain rules and sets up standards with which the mechanical-department officers of the railroad and the railway-supply-company officers, must be familiar. Summarizing, training in the utilization of statistics and reports is a necessary qualification to the mechanical engineer in both the railroad and railroad-supply industries.[7]

### The Railway Organization

In order to understand the part that the mechanical department plays in a railway organization, a brief outline should be given. The organization of a railway company divides itself naturally into several main departments which have clear lines of demarcation. These departments are the legal, the traffic, the treasury, the accounting and auditing, the operating, and the maintenance.

Men of mechanical-engineering education are in demand for service in the maintenance and operating departments. The importance of mechanical-engineering training with respect to the work performed is greatest in the maintenance-of-equipment department. The work of the traffic department can be compared to that of the sales department of a manufacturing concern, and in fact it actually does sell the services of the railroad to the shipper and traveler.

The operating department mans and moves the trains, operates the yards, and mans the stations. It is generally considered to be the most important department. Excluding those who started their railroad career in the executive department as secretary to an executive officer or as chief clerk, it is the operating department that supplies the president on most railroads. This fact was evident when collecting the data for Table 3. The figures shown in the left-hand column will not total 79, due to the fact that the majority worked in several departments before becoming president. In other words, 63 of the 79 worked in the executive, financial, or legal department, four in the accounting, etc.

The good operating man seldom finds it desirable to leave railway service to work in any other industry. When he does, it is to take a position where the executive qualities of leadership bring him greater reward.

TABLE 3 CAREERS OF THE PRESIDENTS OF 79 CLASS I RAILROADS

| | Total | Common school | High school or equiv. | College graduate | College graduates, per cent |
|---|---|---|---|---|---|
| Education | 79 | 33 | 12 | 34 | 43 |
| Department in which trained: | | | | | |
| Executive, financial, legal | 63 | 29 | 6 | 28 | 44.4 |
| Accounting | 4 | 3 | 1 | 0 | 0 |
| Traffic and claims | 13 | 8 | 4 | 1 | 7.7 |
| Operating and telegraph | 42 | 22 | 9 | 11 | 26 |
| Purchasing | 5 | 2 | 2 | 1 | 20 |
| Mechanical | 3 | 2 | 0 | 1 | 33 |
| Engineering, bridges, and signals | 25 | 9 | 2 | 14 | 56 |

As shown in Table 3, the engineering or maintenance-of-way department is another that has always seemed to have received proper recognition. Many railroad division engineers or chief engineers have succeeded in stepping over into the operating department and thus proceeded on their way to the top. The list of railway presidents who started in railway service as rodmen or transitmen is quite a long one. This information is of interest to the mechanical engineer, whose technical education is similar in many respects to that of the civil engineer.

[6] "The Regulation of the Railways," by Samuel O. Dunn. Published by D. Appleton and Company, New York.

[7] "Economics of Railway Operation," by M. L. Byers, Chairman, Valuation Committee, Seaboard Air Line. Published by McGraw-Hill Book Company, New York.

### The Mechanical Department

Generally speaking, the mechanical department is usually subordinated to the transportation department. It seems to lack a class consciousness and in this respect is quite different from the engineering department. The mechanical department is in charge of the design of cars and locomotives, and of their maintenance in good order. No less than 25 per cent of all railway operating expenses and from one-half to two-thirds of the expenditures for capital improvements come under the jurisdiction of this department. This shows that the job of the mechanical-department officer is one of importance and great responsibilities and requires a man capable of exercising mature judgment.

This statement is undoubtedly emphasized by the figures given in Table 4, which shows the years required for mechanical engineers to reach certain positions in the mechanical department of a railroad. One mechanical engineer worked for 49 years before becoming head of the mechanical department of his road. Another worked for 10 years. The average time required for all those of whom the Sub-Committee obtained complete data was 22.8 years.

TABLE 4 YEARS REQUIRED FOR MECHANICAL ENGINEERS TO REACH CERTAIN POSITIONS IN THE MECHANICAL DEPARTMENT OF A RAILROAD

| | Longest time | Shortest time | Average |
|---|---|---|---|
| General supt. of motive power or head of mechanical department | 49 | 10 | 22.8 |
| Assistant or division supt. of motive power | 36 | 7 | 18.8 |
| Mechanical engineer | 33 | 4 | 15.2 |
| Assistant mechanical engineer | 11 | 4 | 8 |
| Engineer of tests | 19 | 5 | 9.75 |
| Engineer of motive power | 24 | 7 | 18 |

Table 5, which shows the number of years that have been required for mechanical engineers to reach certain railroad executive positions, cannot be considered as indicative of the actual opportunities afforded members of the profession in reaching the positions mentioned. Changing conditions in the railroad industry will, in all probability, see more mechanical engineers as railroad presidents. This is perhaps illustrated by the fact that there are now six vice-presidents who have come up from the mechanical department. The office of chief purchasing officer is also included in this table on account of the fact that some railroad managements consider technical training to be a necessary requirement for the duties of this position. At the present time three mechanical engineers are serving as chief purchasing officers.

TABLE 5 YEARS REQUIRED FOR MECHANICAL ENGINEERS TO REACH CERTAIN RAILROAD EXECUTIVE POSITIONS VIA THE MECHANICAL DEPARTMENT

| | Number of officers | Longest time | Shortest time | Average |
|---|---|---|---|---|
| President | 1 | 38 | .. | 38 |
| Vice-president | 6 | 40 | 11 | 30.3 |
| Chief purchasing officers | 3 | 35 | 26 | 32.1 |

### Interests of Railroads and the Railroad-Supply Industry Closely Interwoven

The interests of the railroads and the railroad-supply industry are so intimately interwoven that it is impossible to separate them. The railroads are interested in furnishing that standard of transportation which will best meet the public requirements. They are specialists in transportation, and that in itself is no mean task. They are large purchasers of material and supplies, which is indicated by the fact that for several years—since and including 1920—the Class I railroads have expended in excess of a billion dollars a year, chargeable to the operating account for materials and supplies, exclusive of fuel for locomotives.

The railway-supply manufacturers, specializing on the development, production, and sale of equipment and supplies and enjoying plenty of competition, have made a remarkable contribution to the railroads and the public served by them. The supply manufacturer must keep in intimate contact with the railway operating problems and practices. He frequently goes to the railroads for men for important places in his organization, and relieves the railroad organizations of production details which they are not in a position to handle.

### Facts Relative to the Railroad-Supply Industry

Over 40 per cent of the executive and technical officers and sales staffs of railway-supply concerns, promoted since December, 1919, have either started or worked some time in their careers for a railroad. Approximately 500 manufacturing companies engaged in selling supplies to the railroads, wholly or in part, are listed in the Pocket List of Railroad Officials. Table 6 shows the number of companies engaged in manufacturing and selling certain classes of material, the railroad department responsible for selecting each class of material and its utilization, and the department from which men are usually recruited by the supply companies. These supply companies employ approximately 7000 men as executives and sales engineers, a large proportion of whom the Sub-Committee has good reason to believe are men of technical education. There are also about 40 private-car companies which own and operate over 1000 cars which should also have need for a limited number of mechanical engineers. Five trade magazines published to serve the interests of the railroad industry employ a limited number of mechanical engineers on their editorial and business staffs. These publications, however, employ only mechanical engineers who have had considerable railroad experience.

TABLE 6 CLASSIFICATION OF APPROXIMATELY 500 RAILWAY-SUPPLY COMPANIES ACCORDING TO PRODUCT

| Material sold to railroads | Number of companies | Railway department concerned | Railway department from which men are usually recruited |
|---|---|---|---|
| Air-brake equipment and supplies | 11 | Mechanical<br>Operating | Mechanical<br>Operating |
| Car builders | 24 | Traffic<br>Mechanical | Mechanical |
| Car equipment and appliances | 148 | Mechanical<br>Operating | Mechanical |
| Electric-railway equipment | 25 | Mechanical<br>Electrical | Electrical |

### How the College Man Can Gain Promotion

If the mechanical engineer starts at the bottom of the ladder on graduation from college, he can expect to follow one of five general routes for both the railroad and railroad-supply industries inclusive. Referring to Fig. 1, these general routes are lettered consecutively from *A* to *F*. These routes were charted from

replies to question (*h*)[8] in the questionnaires sent to a selected list of railroad and railway-supply companies, and from an analysis of the careers of various railroad and railroad-supply officers. The dotted lines show some of the transfers which have actually been made by men between the two allied industries. In this connection, it is well to keep in mind that the men who have transferred from railroad to railway-supply companies, and vice versa, have been able to do so on the experience or record attained in either one of the two industries. In other words, the essential experience and requirements for both the railroad and railroad-supply industries are, from all practical standpoints, basically the same.

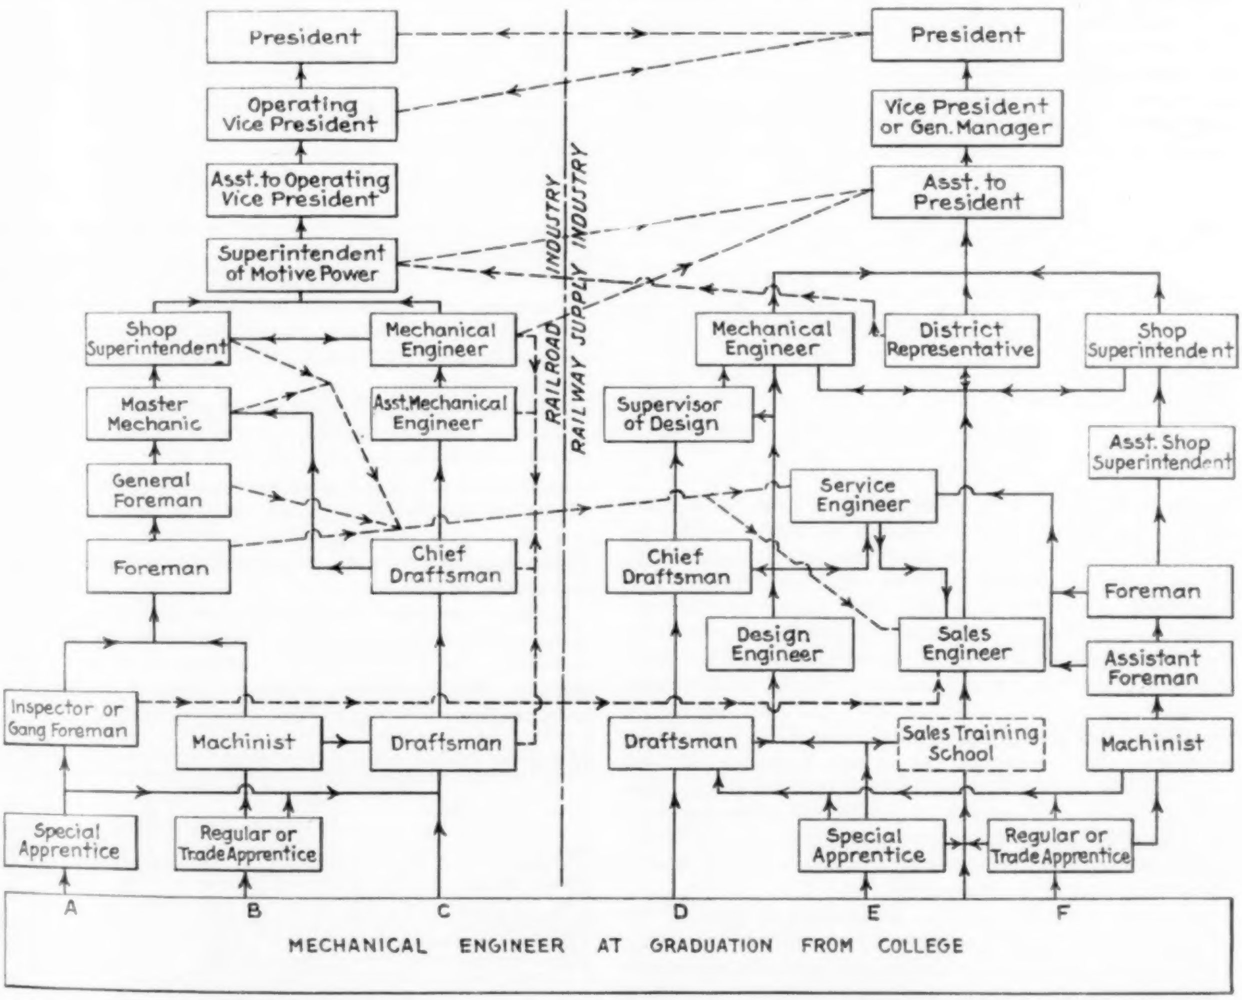

FIG. 1 CHART SHOWING THE GENERAL RATES OF PROMOTION USUALLY FOLLOWED IN THE RAILROAD AND RAILROAD-SUPPLY INDUSTRIES

The Sub-Committee on Professional Service does not wish to convey the impression that each man must necessarily follow one of the five general routes shown in Fig. 1 to get to the top. Analysis of the careers of railroad and railroad-supply officers shows that some have jumped from one route to another or skipped one or more positions in the usual direct line of promotion. There have been instances where special apprentices have become machinists, and there have also been instances of promotion to foremen on the completion of the special apprentice course. It depends on the characteristics and ability of the individual whether he moves slowly or rapidly to higher positions of responsibility.

### Seniority Rules Delay Promotion

The seniority rules are generally admitted to slacken the rate of promotion for the college man in railroad work, but present no insurmountable barrier if superior capacity is demonstrated. The prime necessity of not impairing morale among the employees by anything savoring of favoritism is stressed very generally, although seniority, it is said, will give way to demonstrated superior capacity to fill a higher post. In other words, the burden of proof, "the risk of non-persuasion," must be arrived at by the college man who aspires to promotion in competition with the man of longer service.[9]

Among the facts the young mechanical engineer would like to know before entering the employ of any company are those relating to the manner in which promotion is gained. In other words, must he play politics? be a relative of some high officer, either through birth or marriage? or is promotion gained solely

[8] See the progress report of the Railroad Division's Sub-Committee on Professional Service in the February, 1927, issue of *Mechanical Engineering.*

[9] See abstract of paper by Winthrop M. Daniels, Yale University, read at the annual meeting of the American Economic Association, Chicago, December 30, 1924. February 7, 1925, *Railway Age,* page 375.

through merit? Naturally such information is practically impossible to obtain until one has been in the employ of the company for a time and has had an opportunity to discover some of the inside workings. Fortunately, the majority of the Class I railroads have such large organizations that family influence and politics do not have much weight in obtaining promotion. In fact, a careful check of various records and statistics of the ownership and official personnel of the railroads shows that "family controlled" companies are few in number and are practically all small roads.

Analysis of the careers of officers in both the railroad and railway supply industries shows that the college graduate has a distinct advantage over the non-college man. Reference is made to Tables 7 to 9, inclusive. Table 7 shows the results of a study made of the railroad careers of 25 railroad officers in six different grades. The right-hand column of the table shows the number of years gained by the college graduate in reaching each position listed over the time required by the non-college man in reaching the same position. The officers, selected at random, are all employed by Class I railroads.

TABLE 7 AVERAGE AGES OF 25 RAILROAD OFFICERS IN EACH GRADE SHOWN, TIME REQUIRED TO REACH CERTAIN POSITIONS, AND TIME GAINED BY COLLEGE GRADUATES

| | Average age, years | Average time in R.R. service, years | College trained, per cent | Average time for non-college man, years | Average time for college graduate, years | Time gained by college graduate, years |
|---|---|---|---|---|---|---|
| President | 58.3 | 30 | 53 | 34 | 24 | 10 |
| Vice-president | 50.8 | 28.1 | 48 | 30.7 | 25.2 | 5.5 |
| General manager | 49 | 30.5 | 16.8 | 31.4 | 26.2 | 5.2 |
| Superintendent of motive power | 43.8 | 25.8 | 44 | 29.9 | 19.9 | 10 |
| Mechanical engineer | 35 | 13.75 | 80 | 14.6 | 13.5 | 1.1 |
| Master mechanic | 47.4 | 22.7 | 20 | 24.1 | 15.2 | 9.4 |

In studying this table it is well to keep in mind the fact that the superintendent of motive power is the active head of the mechanical department. A master mechanic is head of the repair shops of a division, and quite often has charge of both locomotive and car repairs. On most roads, however, the master mechanic has only locomotive maintenance to supervise. The mechanical engineer usually reports to the superintendent of motive power, and his work generally pertains to the design, alteration, and selection of rolling stock and shop equipment. Practically all of the mechanical engineers in Table 7 are college graduates. Those who are not college graduates obtained their technical training at night school or by home study. This accounts for the small gain of 1.1 year by the college man over the non-college man. In other words, practically all of the mechanical engineers employed by the railroads have had a college education or its equivalent.

The Sub-Committee felt it to be essential to have all the information contained in this report of as recent date as possible. Table 8 shows the careers of officers holding certain representative positions in railway-supply-manufacturing companies. In collecting data for this table, only the careers of officers promoted since December, 1919, were considered. An interesting item in this table is the large number of vice-presidents as compared with officers of lower rank. The reason for having 37 vice-presidents and only 13 general managers and 11 chief engineers is that the functions of the latter officers are quite often handled by men holding the title of vice-president. It is not an uncommon thing to have a "vice-president in charge of engineering" in a railway-supply company or to see the title of "vice-president and general manager."

Tables 8 and 9 are arranged for comparison with Tables 3 and 7. It is interesting to note the similarity in respect to time element between the careers of railroad presidents and the presidents of railway-supply companies. There is also a large degree of similarity in this respect between the vice-presidents in both industries, but a somewhat greater difference in figures appears in the careers of officers of lower rank. This is due largely to the fact that the growth of the railroad-supply industry is comparatively more recent than that of the railroads. Again the college-trained man appears to have a distinct advantage over the non-college man.

TABLE 8 CAREERS OF OFFICERS HOLDING CERTAIN REPRESENTATIVE POSITIONS IN RAILWAY-SUPPLY COMPANIES

| | No. | No. who started on R.R. | No. who started with R.S. Co. | Education: Common school | Education: High school or equiv. | Education: College grads. | Per cent of college grads. |
|---|---|---|---|---|---|---|---|
| President | 28 | 6 | 22 | 4 | 6 | 18 | 55 |
| Vice-president | 37 | 22 | 15 | 10 | 8 | 19 | 51.4 |
| General manager | 13 | 4 | 9 | 2 | 1 | 10 | 77 |
| Chief engineer | 11 | 4 | 7 | 1 | 1 | 9 | 81.8 |
| Manager of sales | 12 | 7 | 5 | 2 | 3 | 7 | 58.3 |
| Railroad representative | 12 | 9 | 3 | 2 | 1 | 9 | 75 |

TABLE 9 AVERAGE AGES, TIME REQUIRED TO REACH CERTAIN POSITIONS, AND TIME GAINED BY COLLEGE GRADUATES —RAILWAY-SUPPLY COMPANIES

| | Average age, years | Average time in R.R. & R.S. service, years | Average time for non-college man, years | Average time for college graduate, years | Time gained by college graduate, years |
|---|---|---|---|---|---|
| President | 56.6 | 27.1 | 35.5 | 22 | 13.5 |
| Vice-president | 47.75 | 28.9 | 32.2 | 23.8 | 8.4 |
| General manager | 44.7 | 29.2 | 32.4 | 26 | 6.4 |
| Chief engineer | 46.25 | 23.2 | 31 | 20 | 11 |
| Manager of sales | 46 | 21.75 | 27.25 | 18.9 | 8.35 |
| Railroad representative | 43 | 27.1 | 20.9 | 3.8 | 17.1 |

The figures shown in Table 9 do not represent an average for perhaps the four lower grades, but only a limited number as is indicated by the figures shown in Table 8.

Table 10 is arranged for comparison with Table 4. Higher officers are included in Table 10, however, owing to the fact that the duties and responsibilities of many railway-supply-company executives involve problems that are of a mechanical-engineering nature.

It can be said that a large share of the problems confronting the president of the average railway-supply company are similar to those of the superintendent of motive power of a Class I railroad. He should have sufficient technical knowledge to make intelligent decisions on engineering problems.

TABLE 10 YEARS REQUIRED FOR MECHANICAL ENGINEERS TO REACH CERTAIN REPRESENTATIVE POSITIONS IN A RAILWAY-SUPPLY COMPANY

| | Longest time | Shortest time | Average |
|---|---|---|---|
| President | 45 | 15 | 26.8 |
| Vice-president | 39 | 11 | 25.2 |
| General manager | 45 | 12 | 29 |
| Chief engineer | 36 | 20 | 26.4 |
| Assistant engineer | 22 | 15 | 19 |
| Manager of sales | 40 | 12 | 21.2 |
| Assistant or district manager of sales | 26 | 11 | 19.6 |
| Railroad representative | 43 | 4 | 21.2 |

## Salaries Paid in the Two Industries

One of the questions asked in the questionnaire mailed to the various railroad and railway-supply companies in 1927 was: What length of time is required for a man to reach a position paying, say, $5000 a year? Summarizing the replies, it may be said that some railroads do not pay this amount. On those railroads that do pay this sum, the time required would be not less than ten years in the ordinary course of advancement. Again summarizing the replies of the railway-supply companies, no definite length of time can be determined—it will vary with conditions and individuals.

A rough comparison of the salaries paid mechanical engineers in the railroad and railroad-supply industries with the salaries paid engineers in all industries is shown in Figs. 2 to 4, inclusive.

A tabulated analysis of the earnings of engineering graduates in all industries is also shown in Table 11. The data shown in this table and plotted in Fig. 2 were supplied to the Society for the Promotion of Engineering Education by cooperative committees from the faculties of a large number of technical institutions in connection with an investigation made by that society in 1924. The information was obtained by the faculty committees from the alumni of their respective institutions.

TABLE 11 ANALYSIS OF EARNINGS OF ENGINEERING GRADUATES IN ALL INDUSTRIES AS OF JUNE 1, 1924*

| | | | Annual Earnings, in Dollars | | | | |
|---|---|---|---|---|---|---|---|
| Class | Years since graduation | Number reporting | Limit of lowest 25 per cent | Median | Limit of highest 25 per cent | Maximum | Most frequent |
| 1924 | 0 | 1,191 | 1,200 | 1,476 | 1,560 | 4,080 | 1,200 |
| 1923 | 1 | 1,218 | 1,560 | 1,800 | 1,980 | 5,100 | 1,800 |
| 1922 | 2 | 1,023 | 1,800 | 2,100 | 2,400 | 9,000 | 1,800 |
| 1919 | 5 | 309 | 2,400 | 2,860 | 3,500 | 25,000 | 3,000 |
| 1914 | 10 | 498 | 3,110 | 4,000 | 5,100 | 50,000 | 5,000 |
| 1909 | 15 | 430 | 3,600 | 5,000 | 8,000 | 49,500 | 6,000 |
| 1904 | 20 | 238 | 4,000 | 5,500 | 10,000 | 90,000 | 4,000 |
| 1894 | 30 | 116 | 4,500 | 7,500 | 15,000 | 100,000 | 6,000 |
| | Total | 5,023 | | | | | |

* "Study of Engineering Graduates," published by the Society for the Promotion of Engineering Education, p. 287.

TABLE 12 MAXIMUM, MINIMUM, AND AVERAGE ANNUAL SALARIES PAID FOR CERTAIN REPRESENTATIVE POSITIONS OR THEIR EQUIVALENTS IN THE MECHANICAL DEPARTMENT OF A RAILROAD IN 1921

| | Maximum | Minimum | Average |
|---|---|---|---|
| General superintendent of motive power or head of mechanical department | $25,000 | $4,500 | $8,430 |
| Assistant or division superintendent of motive power | 10,200 | 4,000 | 6,660 |
| Mechanical engineer | 11,320 | 4,000 | 5,410 |
| Assistant mechanical engineer | 9,600 | 3,700 | 4,930 |
| Engineer of tests | 10,000 | 4,000 | 5,680 |
| Engineer of motive power | 8,000 | 4,000 | 5,940 |

Table 12 shows the maximum, minimum, and average salaries paid for six representative positions in the mechanical department of a railroad. These data together with the data from which the curves in Fig. 3 were plotted was obtained from a report of hearings before the Committee on Interstate Commerce, United States Senate, in 1921. The median and minimum curves are undoubtedly somewhat higher after five years

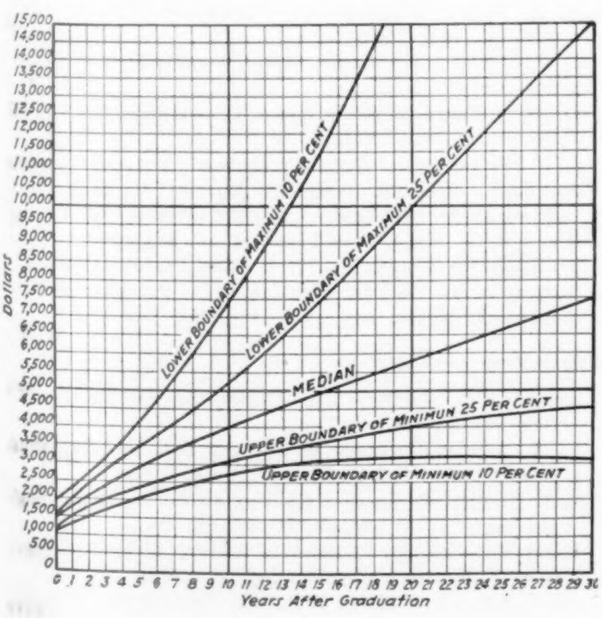

FIG. 2 CHART SHOWING THE EARNINGS OF ENGINEERS IN ALL INDUSTRIES BY YEARS AFTER THEIR GRADUATION FROM UNIVERSITIES AND COLLEGES

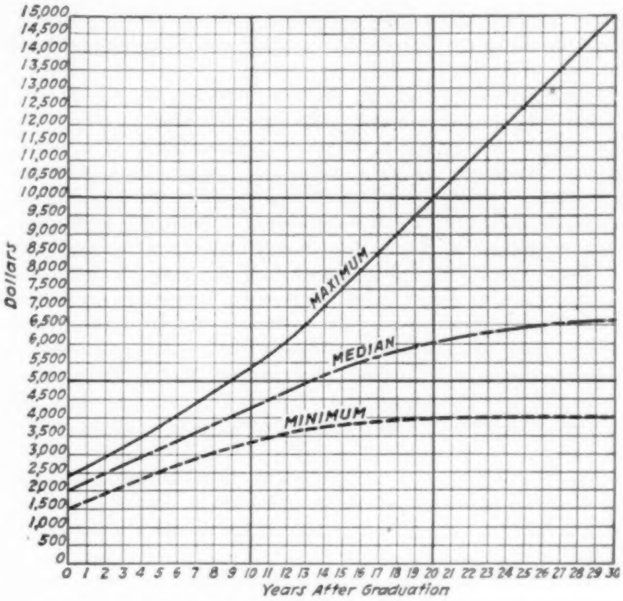

FIG. 3 CHART SHOWING THE EARNINGS OF MECHANICAL ENGINEERS EMPLOYED BY RAILROADS UP TO AND INCLUDING THE POSITION OF CHIEF OF MOTIVE POWER

out of college than they should be, due to the fact that complete data pertaining to salaries paid to draftsmen, foremen and similar grades were not available. Furthermore, the Senate Committee report only included salaries of $5000 and over. Only a few of the salary figures given in the report were less than $5000. Considerable additional data relative to positions paying less than $5000 were obtained from a number of railroads, but the Sub-Committee was unable to check enough of these salary figures against individual careers to plot what it considers to be proper minimum and median curves for all positions in the mechanical department of a railroad. Therefore it must be assumed that Fig. 3 shows only the salaries paid to officers in the mechanical department of a railroad. It does not show the

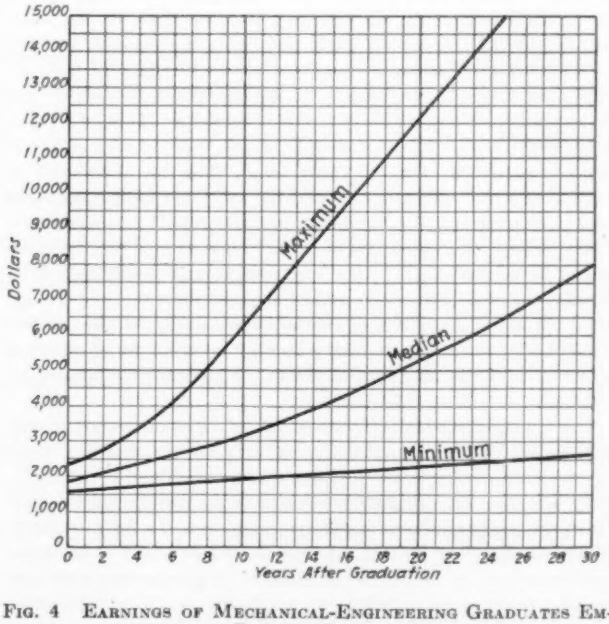

FIG. 4 EARNINGS OF MECHANICAL-ENGINEERING GRADUATES EMPLOYED BY RAILWAY-SUPPLY COMPANIES

salaries paid to officers in executive positions, neither does it show the salaries paid to men not holding some position of official capacity after five years out of college.

Fig. 4 shows the earnings of mechanical engineers employed by railway-supply concerns. The data for these curves were obtained from responsible officers of approximately 20 railway-supply companies. It will be noted that the maximum is higher than that for railroad employees in Fig. 3, but the median and minimum curves are considerably lower. This is due to the fact that complete data on all the mechanical engineers employed by these companies were reported and, of course, include the "square pegs in round holes," something which is not shown in Fig. 3 and, in all probability, not in Fig. 2. Of course, there being a considerably larger number of men working at salaries ranging around $3000 than at salaries of $6000, the median curve in Fig. 4 also is lower than those in Figs. 2 and 3. It is the opinion of the Sub-Committee that the salary situation as shown by the wide area between the maximum and minimum curves in Fig. 4 is a fairly accurate picture of the earnings of the mechanical engineer in industry, taken as a whole. Salaries paid at the present time have experienced no marked change since 1920.

Any attempt to obtain accurate data relative to salaries, such as those paid in the mechanical-engineering profession, presents a number of difficulties that should be taken into consideration when studying the salary data presented here. In the first place, all the men whose salaries are included in the figures are employed. No allowance has been made for those who are unemployed. Secondly, there is a greater possibility of obtaining salary figures from individuals in higher positions than from those who have made little or no progress in the profession. In all probability, curves showing average salaries paid would be much lower than those shown by the median curves in the three salary charts. In other words, a mechanical engineer of average ability can hardly assume that he will earn $4000 when ten years out of college and $6000 twenty years after graduation.

## Conclusion

It is the belief of the Railroad Division's Sub-Committee on Professional Service that if the young mechanical engineer or mechanical-engineering student is convinced that he will like railroad or railroad-supply work and has a special aptitude for such work he will succeed in getting ahead in either of the two allied industries. The degree of success depends largely on the characteristics and ability of the individual. This, of course, holds true for all industries as well as the railroad and railroad-supply industries. On the other hand, it is the consensus of opinion that both the railroads and the railway-supply companies need the young technical graduate, and this report would indicate that in salary and opportunity he can hope to achieve the same degree of success as in other engineering and industrial lines. Finally, the Sub-Committee wishes to stress the value of personal investigation in ascertaining the facts pertaining to the opportunities afforded in any industry he may be thinking of entering before arriving at any final decision, or committing himself to a definite line of work.

The appendixes which follow contain information for the benefit of those who wish to inquire further into the training and work for mechanical engineers on a number of Class I railroads. They also contain information relative to the training afforded by one of the leading railway supply companies, and a list of railway officers in charge of special apprentice work or heads of mechanical departments, to whom the student or graduate mechanical engineer can write relative to employment. For additional information, see the Pocket List of Railroad Officials, published quarterly by the Railway Equipment and Publication Company, 424 W. 33rd Street, New York.

(*Signed*)

Sub-Committee on Professional Service:

Marion B. Richardson, *Chairman*, Associate Mechanical Editor, *Railway Age*, and Associate Editor, *Railway Mechanical Engineer*, 30 Church St., New York.

Eliot Sumner, *Vice-Chairman*, Representing the Railroad Industry, Superintendent of Motive Power, Pennsylvania Railroad, Pennsylvania Station, New York.

Robert S. McConnell, *Vice-Chairman*, Representing the Railroad-Supply Industry, Chief Engineer, Baldwin Locomotive Works, 500 N. Broad St., Philadelphia, Pa.

A. J. Wood, *Vice-Chairman*, Representing the Colleges, Professor of Mechanical Engineering, The Pennsylvania State College, State College, Pa.

*Representing the Railroad Industry*

H. N. Rodenbaugh, Vice-President, Florida East Coast, Marviento, St. Augustine, Fla.

A. G. Trumbull, Chief Mechanical Engineer, Erie, 50 Church St., New York.

Charles E. Barba, Mechanical Engineer, Boston & Maine, 11 Willard St., Newton, Mass.

Wm. Elmer, Special Engineer, Pennsylvania, Philadelphia, Pa.

R. W. Salisbury, Mechanical Engineer, Texas & Pacific, 5818 Belmont Ave., Dallas, Tex.

W. G. Edmondson, Assistant Engineer of Motive Power, Reading Co., Reading, Pa.

Dennistoun Wood, Engineer Tests, Southern Pacific, 809 Lincoln Ave., Palo Alto, Cal.

Edw. Sears, Division Master Mechanic, Chicago, Milwaukee & St. Paul, Deer Lodge, Mont.

*Representing the Railroad-Supply Industry*

D. C. Buell, Director, Railway Educational Bureau, 1809 Capitol Ave., Omaha, Neb.

H. B. Oatley, Vice-President, Superheater Company, 17 E. 42nd St., New York.

D. F. Crawford, Locomotive Stoker Co., Robinson & Darragh Sts., Pittsburgh, Pa.

Harry S. Hammond, Sales Agent, Pressed Steel Car Co., 55 Broad St., New York.

A. F. Stuebing, Chief Engineer, Bradford Corp., New York.

Joseph C. McCune, Assistant Director of Engineering, Westinghouse Air Brake Company, Wilmerding, Pa.

Wm. E. Woodard, Vice-President of Engineering, Lima Locomotive Works, Inc., 17 E. 42nd St., New York.

Montague H. Roberts, Vice-President, Franklin Railway Supply Company, Inc., 17 E. 42nd St., New York.

*Representing the Colleges*

Samuel Wm. Dudley, Yale University, 400 Temple St., New Haven, Conn.

R. A. Norman, Professor of Mechanical Engineering, Iowa State College, 715 Park Ave., Ames, Iowa.

L. E. Endsley, Professor of Railway Mechanical Engineering, University of Pittsburgh, Pittsburgh, Pa.

Harry Rubenkoenig, Professor of Railway Mechanical Engineering, Purdue University, Lafayette, Ind.

Ed. C. Schmidt, Professor of Railway Engineering, University of Illinois, Urbana, Ill.

John W. Fountain, Jr., Assistant Coordinator, Cooperative Department, Georgia School of Technology, Atlanta, Ga.

ADVISORY MEMBERS EX-OFFICIO

*Representing the A.S.M.E. Committee on Relations with the Colleges*

W. H. Kavanaugh, Prof. of Experimental Engineering, Towne Scientific School, University of Pennsylvania, Phila., Pa.

*Representing the A.S.M.E. Committee on Education and Training for the Industries*

John T. Faig, President, Ohio Mechanics Institute, Cincinnati, Ohio.

*Representing the A.S.M.E. Standing Committee on Professional Divisions*

Robert T. Kent.

*Representing the Society for the Promotion of Engineering Education*

H. P. Hammond, Associate Director, 33 West 39th St., N. Y.

*Representing the Mechanical Division, A.R.A.*

E. Sears, Division Master Mechanic, Chicago, Milwaukee & St. Paul, Deer Lodge, Mont.

John L. Harrington, Harrington, Howard & Ash, 1012 Baltimore Ave., Kansas City, Mo.

## Appendix No. 1

LIST OF OFFICERS IN CHARGE OF APPRENTICES

A list of railroad officers in charge of special apprentices to whom the student or mechanical-engineering graduate should write for information relative to employment, follows. This list is subject to change, but can be brought up to date by comparing with the Pocket List of Railroad Officials and checking the title and address with the name. The company list, however, is permanent.

| Railroad | Name | Title | Address |
|---|---|---|---|
| **NEW ENGLAND REGION** | | | |
| Boston & Albany | F. A. Butler | Supt. M. P. & R. S. | Boston, Mass. |
| Boston & Maine | L. Richardson | Mech. Supt. | Boston, Mass. |
| N. Y., N. H. & Hartford | H. P. Hass | Asst. to Mech. Eng. | New Haven, Conn. |
| **GREAT LAKES REGION** | | | |
| Delaware & Hudson | G. S. Edmonds | Supt. M. P. | Albany, N. Y. |
| | G. W. Ditmore | M. C. B. | Albany, N. Y. |
| D. L. & W. | C. J. Scudder | Supt. M. P. & E. | Scranton, Pa. |
| Erie | W. S. Jackson | Supt. M. P. | 50 Church St., New York |
| Lehigh Valley | F. N. Hibbits | Supt. M. P. | Bethlehem, Pa. |
| Michigan Central | J. F. Jennings | Supt. M. P. | Detroit, Mich. |
| New York Central | W. H. Flynn | Genl. S. M. P. & R. S. | 466 Lexington Ave., New York |
| N. Y. C. & St. L. | T. W. Coe | Supt. M. P. | Prospect Ave. & E. 2nd St., Cleveland, O. |
| Pere Marquette | R. J. Williams | Supt. M. P. | Detroit, Mich. |
| Pitts. & Lake Erie | K. Berg | Supt. M. P. | McKees Rocks, Pa. |
| Wabash | G. F. Hess | Supt. M. P. | Decatur, Ill. |

## Appendix No. 2

### INFORMATION RELATIVE TO EMPLOYMENT

A list of railway-supply-company officers to whom the student or mechanical-engineering graduate can write for information relative to employment, follows.

| Company | Name | Title | Address |
|---|---|---|---|
| Adams & Westlake Co. | W. H. Baldwin | Vice-Pres. | 319 W. Ontario St., Chicago, Ill. |
| Air Reduction Sales Co. | E. M. Sexton | R.R. Sales Mgr. | 346 Madison Ave., N. Y. C. |
| American Arch Co., Inc. | John P. Neff | Vice-Pres. | 17 E. 42nd St., N. Y. C. |
| American Brake Shoe & Fdry. | W. S. McGowan | Vice-Pres. | 30 Church St., N. Y. C. |
| American Car and Foundry Co. | Victor R. Willoughby | Gen. Mech. Eng. | 30 Church St., N. Y. C. |
| American Locomotive Co. | Joseph B. Ennis | Vice-Pres. | 30 Church St., N. Y. C. |
| American Ry. Appliance Co. | A. Schneider | President | 350 Madison Ave., N. Y. C. |
| American Steel Foundries | R. P. Lamont | President | Wrigley Bldg., Chicago, Ill. |
| Ashton Valve Co. | J. W. Motherwell | Vice-Pres. & Gen. Mgr. | Boston, Mass. |
| Baldwin Locomotive Works | R. S. McConnell | Ch. Eng. | Philadelphia, Pa. |
| Barco Manufacturing Co. | F. N. Bard | President | 1801 Winnemac Ave., Chicago, Ill. |
| Bethlehem Steel Company | J. M. DesIslets | Steel Car Div. | Bethlehem, Pa. |
| Bettendorf Co. | J. W. Bettendorf | President | Bettendorf, Ia. |
| Bird-Archer Co. | C. A. Bird | Vice-Pres. | 1 E. 42nd St., N. Y. C. |
| Bradford Corp. | A. F. Stuebing | Chief Engr. | 25 W. 43rd St., N. Y. C. |
| J. G. Brill Co. | J. L. Poultney | Mech. Eng. | 62nd St., Phila., Pa. |
| Buckeye Steel Castings Co. | S. P. Bush | President | Columbus, Ohio |
| Buda Company | F. E. Place | Vice-Pres. | Harvey, Ill. |
| Camel Co. | Fred. C. Heinen | Manager | 332 S. Michigan Ave., Chicago, Ill. |
| Chicago Ry. Equipment Co. | E. E. Griest | Gen. Supt. | 1928 W. 46 St., Chicago, Ill. |
| Cincinnati-Bickford Tool Co. | August H. Tuechter | President | Cincinnati, Ohio |
| Clark Car Co. | Chas. H. Clark | President | Oliver Bldg., Pittsburgh, Pa. |
| Commonwealth Steel Co. | C. H. Howard | President | Granite City, Ill. |
| Fairbanks, Morse & Co. | P. H. Gilleland | Mgr. R.R. Div. | 900 S. Wabash Ave., Chicago, Ill. |
| Franklin Ry. Supply Co. | Chas. G. Carothers | Mech. Eng. | 17 E. 42nd St., N. Y. C. |
| Gold Car Heating & Lighting Co. | E. B. Wilson | Vice-Pres. | 220 36th St., Brooklyn, N. Y. |
| Gould Coupler Co. | C. J. Symington | President | Md. Trust Bldg., Baltimore, Md. |
| Hunt-Spiller Mfg. Corp. | W. B. Leach | Pres. & Gen. Mgr. | 383 Dorchester Ave., Boston, Mass. |
| Hyatt Roller Bearing Co. | H. J. Forsythe | President | Newark, N. J. |
| Illinois Car & Mfg. Co. | ........... | ....... | Hammond, Ind. |
| Ingersoll-Rand Co. | L. G. Coleman | Mech. Eng., R.R. Div. | 11 Broadway, N. Y. C. |
| Johns-Manville | Geo. A. Nicol, Jr. | Gen. Mgr., R.R. Dept. | 292 Madison Ave., New York, N. Y. |
| R. K. LeBlond Mch. Tool Co. | John A. LeBlond | Vice-Pres. | Madison Road, Cincinnati, Ohio |
| Lima Locomotive Works | W. E. Woodard | Vice-Pres. | 17 E. 42nd St., N. Y. C. |
| Locomotive Firebox Co. | B. E. Larson | Mech. Eng. | 310 S. Michigan Ave., Chicago, Ill. |
| Lukens Steel Co. | D. S. Wolcott | Asst. to Pres. | Coatesville, Pa. |
| Magor Car Corp. | A. Van Hassel | Vice-Pres. | 30 Church St., N. Y. C. |
| Manning, Maxwell & Moore, Inc. | Frank J. Baumis | Vice-Pres. | 100 E. 42nd St. N. Y. C. |
| W. H. Miner, Inc. | W. H. Miner | President | 209 S. LaSalle St., Chicago, Ill. |
| New York Air Brake Co. | Richard B. Sheridan | Vice-Pres. | 165 Broadway, N. Y. C. |
| Niles-Bement-Pond Co. | J. K. Cullen | President | 111 Broadway, N. Y. C. |
| Ohio Brass Co. | L. W. Birch | Line Matl. Eng. | Mansfield, Ohio |
| Oxweld R.R. Service Co. | Chas. B. Moore | Vice-Pres. | 350 Ry. Ex. Bldg., Chicago, Ill. |
| Pressed Steel Car Co. | Huntley H. Gilbert | Gen. Sales Mgr. | 134 LaSalle St. Chicago, Ill. |
| Pullman Car & Mfg. Corp. | Peter Parke | Chief Engr. | Pullman Bldg., Chicago, Ill. |
| Q. & C. Co. | F. F. Kister | President | 90 West St., N. Y. C. |
| Railroad Supply Co. | E. H. Bell | President | 203 S. Dearborn St., Chicago, Ill. |
| Railway Motors Co. | L. W. Melcher | ....... | DePere, Wis. |
| S. K. F. Industries, Inc. | W. L. Batt | President | 40 E. 34th St., N. Y. C. |
| Safety Car Heating & Lighting Co. | J. H. Dixon | Vice-Pres. | 75 West St., N. Y. C. |
| St. Louis Car Co. | ........... | ....... | 8000 N. Broadway, St. Louis, Mo. |
| Sinclair Refining Co. | Clifford M. Larson | Supvr. Eng. Ry. Sales Dept. | 45 Nassau St., N. Y. C. |
| Standard Steel Car Co. | John H. Mitchell | Mgr. Sales | 1120 Frick Bldg., Pittsburgh, Pa. |
| Standard Stoker Co. | F. C. Pickard | Works Mgr. | Erie, Pa. |
| Superheater Co. | H. B. Oatley | Vice-Pres. | 17 E. 42nd St., N. Y. C. |
| Symington Co. | C. J. Symington | President | 250 Park Ave., N. Y. C. |
| Timpken Roller Bearing Co. | W. C. Sanders | Gen. Mgr., Ry. Div. | Canton, Ohio |
| Union Draft Gear Co. | L. T. Canfield | Vice-Pres. | 332 S. Michigan Ave., Chicago, Ill. |
| Union Tank Car Co. | Jos. J. Root | Asst. to Vice-Pres. | 134 N. LaSalle St., Chicago, Ill. |
| U. S. Steel Corp. | John Hulst | Asst. to Vice-Pres. | 71 Broadway, N. Y. C. |
| Vapor Car Heating Co., Inc. | Egbert H. Gold | President | 80 E. Jackson Blvd., Chicago, Ill. |

| Whiting Corp. | T. S. Hammond | President | Harvey, Ill. |
| Worthington Pump & Mchy. Corp. | Fred. A. Pope | Supvr. Training | 115 Broadway, N. Y. C. |

## Appendix No. 3

### OUTLINE OF TRAINING COURSES

The following material constitutes an outline of the courses of training given by 20 railroad companies and one railway-supply company to prepare graduates in mechanical engineering for work in the mechanical or motive-power departments. These courses are generally known as special apprentice courses. A number of the companies from which this information was obtained have requested that their identity with the course not be published. The majority of the railroads have an agreement with the shop crafts limiting the total of special, regular, and helper apprentices to five per cent of the total number of machinists and helpers employed. Information relative to any of the courses listed in this Appendix may be obtained by writing to the chairman of the Sub-Committee on Professional Service, Railroad Division, A.S.M.E., 29 W. 39th St., New York.

### RAILROAD "A"

Special apprentices are selected from young men between the ages of 18 and 26 years, who have had a technical-school education and who pass an examination on engineering principles. They must serve a period of three years of 290 days each calendar year, during which time they receive training in the various departments in the different classes of work of the crafts employed in the Maintenance of Equipment department.

If retained in the service at the completion of the three-year course, they select the craft they desire employment in and are given training in the work of the craft selected for the period of one year. During this period, special apprentices are allowed a special rate. At the completion of four years, each special apprentice is classified and he receives the minimum rate of the craft in which he is employed until a vacancy occurs in the supervisory staff.

The rates paid special apprentices are as follows:

| Year | Period | Hourly rate |
|---|---|---|
| First | First six months | $0.52 |
| | Second six months | 0.545 |
| Second | First six months | 0.57 |
| | Second six months | 0.595 |
| Third | First six months | 0.62 |
| | Second six months | 0.65 |
| Fourth | Year | 0.69 |

Special apprentices are promoted to fill vacant minor supervisory positions, their selection and promotion depending entirely on their individual ability and qualifications.

In addition to the shop training, beginning September 1, 1927, this road extends its regular apprentice technical training to the special apprentices. This training gives special instructions pertaining to the work of the various crafts. Special apprentices will, like the regular and helper apprentices, be required to follow a progressive study period and do their studying and prepare their examinations on their own time. The rules of the shop crafts' agreement make this technical training compulsory and each apprentice must submit a minimum of two lessons each month.

This railroad employs the Railway Educational Bureau, Omaha, Neb., to furnish technical training to all regular and helper apprentices. This bureau furnishes the necessary texts and instruction papers to the apprentices, corrects and grades the lessons which are prepared by the apprentices at home; also furnishes the railroad with a monthly report showing the lessons submitted by each apprentice, together with the grades made. All apprentices are required to follow a progressive study schedule and complete two lessons each month. They do their studying and prepare their examinations on their own time.

The technical training of apprentices is directed from the office of the chief of motive power and equipment, where an organization, in charge of the assistant supervisor of shops, supervises the apprentice training and maintains monthly reports showing the individual progress of each apprentice. This technical training was made compulsory prior to putting this plan into effect.

Schedule for Special Apprentices Showing the Time Assigned to Various Classes of Work in the Different Shops and Departments

| | |
|---|---|
| *Erecting Shop* | |
| Tool room (issuing tools)—To obtain general knowledge of tools | 1/2 mo. |
| Steam-tight gang—On checks, pops, whistles, gage cocks, etc. | 1 mo. |
| Steam-pipe gang—On steam pipes, dry pipes, throttle boxes and rigging, etc. (1 week to be spent on grinding and assembling and the remainder on erecting) | 1 mo. |
| Brake rigging | 1/2 mo. |
| Frame gang—Cylinder—1 week; Boiler pads—1 week; Frames and braces—1/2 month | 1 mo. |
| Shoe and wedge gang | 1 mo. |
| Valve gang | 1 1/2 mo. |
| Guide gang | 1/2 mo. |
| Total | 7 mo. |
| *Machine Shop* | |
| Wheel and eccentric gang | 1 mo. |
| Box gang | 1/2 mo. |
| Main and side rods, and crossheads | 1 1/2 mo. |
| Valves | 1/2 mo. |
| Links | 3/4 mo. |
| Throttle rigging and reverse bars | 3/4 mo. |
| Miscellaneous machine work, lathe, planer, boring mill, etc. | 2 mo. |
| Total | 7 mo. |
| *Tool Department* | |
| General machine work | 1 mo. |
| *Air Brake Shop* | |
| Injectors | 1/2 mo. |
| Pop or relief valves | 1/4 mo. |
| Triple valves | 1/4 mo. |
| Engineer's valves | 1/4 mo. |
| Air compressors | 3/4 mo. |
| Total | 2 mo. |
| *Boiler Shop* | |
| Laying out | 1/2 mo. |
| Fitting up | 1/2 mo. |
| General boiler work | 3 mo. |
| Total | 4 mo. |
| *Car Department* | |
| Passenger-car truck work | 1/2 mo. |
| Passenger-car body work | 1/2 mo. |
| Passenger car interior work | 1 mo. |
| Freight track (special work under foreman to get a general idea of car work) | 1 mo. |
| Inspection—Air brakes | 1/2 mo. |
| Inspection—General | 1/2 mo. |
| Total | 4 mo. |
| *Drawing Room* | |
| Freight-car work | 1 mo. |
| Passenger-car work | 1 mo. |
| Locomotive work | 1 mo. |
| (This work to be as general as possible in all three departments) | |
| Total | 3 mo. |
| *Special Work* | |
| Routing system | 1 mo. |
| Shop order | 1/2 mo. |
| Test department (general) | 1 mo. |
| Cost statements | 1/2 mo. |
| Total | 3 mo. |

*Enginehouse*

| | | |
|---|---|---|
| Inspectors | 1/2 | mo. |
| Passenger engines | 1 | mo. |
| Freight engines | 1 | mo. |
| Laid-in gang | 1/2 | mo. |
| Road foreman | 2 | mo. |
| Total | 5 | mo. |

(Work at enginehouses to be distributed on repairs of all parts of engines.)

The assignment of work for the fourth year will be as per special chart for each craft.

Division of Time on Various Classes of Work in Different Grades for Special Apprentices During Fourth Year of Their Apprenticeship

(Special apprentice to choose the craft he desires prior to entering on fourth year.)

*Machinist Craft*

*A*—2 months—air-brake work
*B*—2 months—tool room—tool and die work
*C*—3 months—machine shop—bench and machine work
*D*—3 months—erecting shop—valve, frame, steam and trimming
*E*—2 months—autogenous welding

*Boilermaker Craft*

*A*—2 months—laying out—locomotive boiler, firebox and car sheet metal parts
*B*—2 months—flanging—boiler and firebox parts
*C*—2 months—assembling—boiler and firebox sheets
*D*—2 months—applying stay, radial and flexible bolts—tapping and driving
*E*—2 months—caulking and chipping
*F*—2 months—autogenous welding

*Carmen Craft*

*A*—4 months—freight car department
*B*—2 months—saw mill and cabinet shop
*C*—1 month—passenger car finishing shop
*D*—2 months—passenger car pipe shop
*E*—3 months—passenger car erecting shop

Statement Showing Status of Special Apprentices on Railroad "A"—August 1, 1927

| | |
|---|---|
| Total number authorized | 35 |
| Total number employed since December, 1921[10] | 66 |
| Number left service prior to completing course | 17 |
| Number completed course to date | 19 |
| Number now serving | 30 |

The following shows present status of the 19 who completed courses: eight are not in supervisory positions and ten are working as mechanics on special work at mechanic's rate.

## RAILROAD "B"

### Special Apprenticeship Course

The purpose of the course is to train for official positions in the motive power department graduates in mechanical engineering from universities or colleges whose courses of study in that branch of engineering fit young men to meet our requirements. Application for appointment as special apprentice is made to the chief of motive power, in the handwriting of the applicant on a special form accompanied by a recent photograph of the applicant. If the application is favorably considered, the applicant is given a personal interview by the chief of motive power before a final decision as to his appointment is reached.

In selecting the young men consideration is given not only to the educational requirements, but also to their personality, physique, and general make-up. Railroad "B" especially desires to secure men with initiative who are interested in and willing to work to learn the railroad business. The course covers a period of three years, divided between the various departments at the principal repair shops of the company, and on the road, as follows:

| | | |
|---|---|---|
| Erecting shop | 6 | mo. |
| Machine shop | 5 | mo. |
| Air-brake shop | 2 | mo. |
| Blacksmith shop | 1 | mo. |
| Iron foundries | 2 | mo. |
| Enginehouse | 4 1/2 | mo. |
| Car shop | 3 | mo. |
| Division superintendent | 3 | mo. |
| Boiler shop | 3 | mo. |
| Firing | 2 | mo. |
| Office road foreman of engines | 1 | mo. |
| Storehouse | 1 | mo. |
| Office of supervisor of expenditures | 1 1/2 | mo. |
| Car-interchange rules | 1 | mo. |
| Total | 36 | mo. |

At the present time the rate of pay for the first six months is 55 cents per hour (208 hours a month), increasing two cents an hour each six months to 65 cents per hour for the final period.

Special apprentices are carried on the payroll the same as other employees, and are paid only for the time worked, no provision being made for vacation.

During his course, the special apprentice is brought into more or less close contact with the officials and learns something of the ethical side of the requirements of an officer of the company.

While there is no contract requiring them to do so, it is, of course, expected that young men taking this course intend to continue in the railroad's service. Upon completion of the course, special apprentices are assigned as motive power inspectors, or as gang foremen in enginehouses, for which positions the present salaries are $230 and $238, respectively, a month. Their subsequent advancement depends upon the general ability and fitness displayed and the openings that may occur in the organization. The line of promotion is usually assistant master mechanic, assistant engineer of motive power, master mechanic, superintendent of motive power, etc.

## RAILROAD "B"

### Special Apprenticeship Courses

*Erecting Shop*

| | | |
|---|---|---|
| General erecting shop work with machinist | 4 | mo. |
| Driving boxes and link work | 3 | wks. |
| Steam pipes, throttles, and air-brake fittings | 3 | wks. |
| Iron pipes and back-head fittings | 2 | wks. |
| Total | 6 | mo. |

*Machine Shop*

| | | |
|---|---|---|
| Planer, by himself | 1 | mo. |
| Slotter, by himself | 1 | mo. |
| Boring mill | 1/2 | mo. |
| Bench work on main rods | 1/2 | mo. |
| Lathe, by himself | 1 | mo. |
| Bench work on links, crossheads, pistons | 1/2 | mo. |
| Laying-off table | 1/2 | mo. |
| Total | 5 | mo. |

*Air-Brake Shop*

| | | |
|---|---|---|
| Injectors | 1 | wk. |
| Triple valves | 1 | wk. |
| Lubricators and retaining valves | 1 | wk. |
| Test racks | 1 | wk. |
| Pump and top heads | 1 | wk. |
| Brake and feed valves | 1 | wk. |
| Regulators, high-speed reducing valves | 2 | wks. |
| Total | 2 | mo. |

*Blacksmith Shop*

| | | |
|---|---|---|
| Hand forge on miscellaneous work | 2 | wks. |
| Hand forge on tools | 1 | wk. |
| Spring shop | 1/2 | wk. |
| Forge or hammer shop | 1/2 | wk. |
| Total | 1 | mo. |

(Apprentices to be given an elementary knowledge of hand forging. Special emphasis to be placed on the dressing and tempering of tools.)

[10] The United States Railroad Labor Board handed down a rule authorizing the employment of special apprentices, effective December 1, 1921.

*Iron Foundries*

| | | |
|---|---|---|
| Cupola | 2 | wks. |
| Helping molders on miscellaneous work | 2 | wks. |
| On cylinders helping molders | 2 | wks. |
| On pipes helping molders | 1 | wk. |
| Wheel foundry helping molders | 1 | wk. |
| Total | 2 | mo. |

*Enginehouse*

| | | |
|---|---|---|
| Machinist gang | 2½ | mo. |
| Air brake gang | ½ | mo. |
| Inspection pit | ½ | mo. |
| Work distributor | ½ | mo. |
| Cleaning fires and moving engines | ¼ | mo. |
| Office work, chasing power | ¼ | mo. |
| Air-brake instruction room | — | |
| Total | 4½ | mo. |

*Car Shops*

| | | |
|---|---|---|
| Freight cars (new and repair work, attending wrecks) | 1 | mo. |
| Steel car shop (all operations on runway and miscellaneous work, including running of machines) | 1 | mo. |
| Passenger cars, new and repair work | 1 | mo. |
| Total | 3 | mo. |

*Interchange and Inspection*

| | | |
|---|---|---|
| Car inspection, classification yard (inspecting freight cars, 2 weeks; inspecting passenger cars, 2 weeks) | 1 | mo. |
| Freight car repairs, outside (with gang on repairs, 1 month; with inspector, 1 month) | 2 | mo. |
| Instruction to be given in M.C.B. work | — | |
| Total | 3 | mo. |

*Boiler Shop*

| | | |
|---|---|---|
| Staying, stays and crown bolts | 3 | wks. |
| Bracing | 1 | wk. |
| Patching | 2 | wks. |
| Inspecting in yard and enginehouse | 3 | wks. |
| Flue work | 2 | wks. |
| Sheet iron work | 1 | wk. |
| Total | 3 | mo. |
| Firing freight and passenger runs (assignment of runs to be made by road foreman of engines) | 2 | mo. |
| Office of road foreman of engines | 1 | mo. |

*Storehouse*

| | | |
|---|---|---|
| Storehouse | 1 | wk. |
| Receiving and shipping department | 1 | wk. |
| Main storehouse office | 2 | wks. |
| Total | 1 | mo. |

(Apprentices in this department shall be given the opportunity to familiarize themselves with the methods of ordering, receiving and giving out material, together with the records and forms used. They should be taught methods of keeping account of stock and how to maintain a reasonable supply.)

### Shop Accounts

| | | |
|---|---|---|
| Time accounts | 1 | wk. |
| Labor distribution | 1 | wk. |
| Tabulating room | 1 | wk. |
| Cost accounts | 1 | wk. |
| Expense accounts | 1 | wk. |
| Inventory | 1 | wk. |
| Total | 1½ | mo. |

### M.C.B. Interchange

| | | |
|---|---|---|
| Instructions and car interchange rules | 1 | wk. |
| Checking A.R.A. billing repair cards | 1 | wk. |
| Writing A.R.A. car repair bills | 1 | wk. |
| Reports of foreign bad orders and destroyed cars and general interchange matters | 1 | wk. |
| Total | 1 | mo. |

## RAILROAD "C"

Provision is made for a limited number of special apprentices who, as a rule, are required to be graduates of recognized colleges in engineering courses. They are given a general experience in the shops and enginehouses and in road tests and other operations of major importance in railroad mechanical operation. We stress the enginehouse experience as it is in the terminal operations that the individual, in our view, has the best opportunity for his own advancement and of prospective value to us.

If the apprentice has the qualities of success in him he will sooner acquire a true railroad perspective in the enginehouse than in the back shop. We give special apprentices who do not gravitate to the engineering department or some other staff positions a well-rounded experience in all departments of mechanical operation.

Special apprentices are started at 55 cents an hour, at the end of the first year they are raised to 65 cents and advanced to journeyman's rate of 75 cents an hour at the end of the second year. In other words, they get journeyman's rate for the third and last year of apprenticeship. Special apprentices are supervised in general through the superintendent of apprentices through the line officers in charge of our mechanical operations.

## RAILROAD "D"

The following is the information relative to the special apprentice training given by Railroad "D:"

### First Year

Salary—First 6 months, $120; Second 6 months, $124.

(Experience on the regular work in the shops, with change of work approximately every three months.)

### Second Year

Salary—First 6 months, $128; Second 6 months, $132.

(Experience on the regular work in the shops with special assignment, as opportunity offers, to dynamometer car tests and other special duty.)

### Third Year

Salary—First 6 months, $136; Second 6 months, $140.

(Experience on the regular work in the shops, with a period in the enginehouse. Special duty assignments leading to supervisory positions.)

## RAILROAD "E"

### Special Apprentice Course for Mechanical Engineers

#### First Year

Salary—53 and 55 cents per hr.

| Work | No. of weeks |
|---|---|
| Stripping | 2 |
| Machine shop | 8 |
| Wheel shop | 4 |
| Rods, crossheads, etc. | 5 |
| Accessories | 8 |
| Air brakes | 8 |
| Boilers | 9 |
| Spring and brake rigging | 4 |
| Total | 48 |

#### Second Year

Salary—57 and 59 cents per hr.

| | |
|---|---|
| Frames | 8 |
| Trucks | 2 |
| Valve motion | 6 |
| Erecting shop | 5 |
| Tank shop | 2 |
| Enginehouse | 13 |
| Electric locomotive repair shop | 12 |
| Total | 48 |

#### Third Year

Salary—61 and 63 cents per hr.

| | |
|---|---|
| Central power station | 8 |
| Gasoline rail-car shops | 12 |
| Drafting room | 12 |
| Department of tests | 12 |
| Mechanical Engineer's Office | 4 |
| Total | 48 |

## RAILROAD "F"

Special apprentices shall be selected from young men between the ages of 18 and 26 years, who have had at least two years technical school training and shall serve three years of 290 days, or the equivalent in hours, each calendar year. Special apprentices shall receive training in the various departments in the different classes of work of the different crafts in the maintenance of equipment and may be moved from place to place, or on any class of work for the first 18 months. The last 18 months to be devoted to such work as conditions will permit.

## RAILROAD "G"

The course for special apprentices is covered by an agreement between the company and the shop crafts employees, the requirements being as outlined:

"Special apprentices shall be selected from young men between the ages of 18 and 26 years who have had a technical-school education and shall serve three years of 290 days, each calendar year. They shall receive training in the various departments in the different classes of work of the different crafts in the maintenance-of-equipment department and may be moved from place to place or on any class of work at the discretion of the management.

"In computing the ratio of apprentices to mechanics, special apprentices will be included, the number of same not to exceed five per cent of the total. If retained in the service at the completion of the three-year course, the apprentice may choose the craft he desires employment in and shall receive a special rate for the period of one year, at the expiration of which time he shall be classified and receive the minimum rate of the craft employed in. The rate of pay for special apprentices for the first three years shall be not less than that of helper apprentices."

Special apprentices report either to the superintendent of shops or to the mechanical engineer depending on the particular assignment on which they may be working. Generally they are started in the mechanical engineer's office or the shop drafting office on drawing files and other drafting work. Some are placed in the shops at various trades, others continue in the drafting office filling vacancies that occur in the ranks of junior draftsmen.

While it is desired to give all special apprentices a chance to work in all departments of the shops, it is not always possible to do so as when vacancies occur in the ranks of draftsmen, we select the more competent and promote them to these positions. The ones that finally complete the course are generally found to be valuable material for promotion to ranks of shop supervisors.

Railroad "G" has no particular course of study for special apprentices except the training they get in the shops. Being selected from the ranks of technical graduates, they usually are much further advanced than other apprentices and are not required to attend school. Their selection for shop supervisors and other positions of trust and responsibility depend entirely on their ability and experience. Seniority as a rule has nothing to do with promotion except of course, where ability and experience are approximately equal.

The rates of pay are as follows: First six months, 48 cents per hour, with a 2-cent increase each six months thereafter for the first six periods. After completion of the third year, special apprentices are given a special rating for one year.

First Year

Salary—48 cents and 50 cents per hr.

| Work | Weeks |
|---|---|
| Machine shop | 17 or 18 |
| Erecting shop | 17 or 18 |
| Boiler shop | 17 or 18 |

Second Year

Salary—52 cents and 54 cents per hr.

| | |
|---|---|
| Blacksmith shop | 17 or 18 |
| Electric shop | 17 or 18 |
| Foundry | 17 or 18 |

Third Year

Salary—56 cents and 58 cents per hr.

| | |
|---|---|
| Drawing room | 17 or 18 |
| Schedule department | 17 or 18 |
| Locomotive tests | 17 or 18 |

Fourth Year

Salary—special rates are set for individuals by the shop superintendent or master mechanic.

Special work depending on man's ability ......... 52

## RAILROAD "H"

First Year

Salary—50 cents and 55 cents per hr.

| Work | Weeks |
|---|---|
| In machine shop—all classes of work | |
| Machine shop practices | |

Second Year

Salary—60 cents and 65 cents per hr.

Erecting shop practices and finishing machine shop practices

## RAILROAD "J"

First Year

Salary—30 cents and 33 cents per hr.

| Work | Weeks |
|---|---|
| *Machine Shop* | |
| Drill press | 8 |
| Engine lathe | 12 |
| Draw-cut shaper | 8 |
| Turret lathe | 8 |
| Brass lathe | 8 |
| Frames | 4 |
| Welding | 4 |

Second Year

Salary—37 cents and 40 cents per hr.

| | |
|---|---|
| *Erecting Shop* | |
| Cab work | 2 |
| General floor | 4 |
| Rods | 8 |
| Motion work | 10 |
| Shoes and wedges | 4 |
| Air room | 8 |
| Valves | 8 |
| Cross heads | 4 |
| Tool room (milling machine) | 4 |

Third Year

Salary—40 cents and 44 cents per hr.

| Work | Weeks |
|---|---|
| *Boiler Shop* | |
| Flange fire | |
| General boiler work and laying out | 24 |
| *Blacksmith Shop* | |
| Light fire | |
| Bulldozer and heavy forging | 24 |

Fourth Year

Salary—51 cents and 58 cents per hr.

| | |
|---|---|
| *Car Department* | |
| Air and heavy repairs | 24 |
| *Mill and A.R.A.* | |
| Enginehouse, general work and inspecting | 24 |

## RAILROAD "K"

Technical graduates who are accepted as special apprentices put in certain time in the drafting room, after which they are transferred to different shop points on the railroad where they work in various departments of the shop operation. As a general thing they are occasionally given special assignments such as economic studies for new equipment and improvements, and some test work. An attempt is made to keep them in the shop on actual work to the greatest extent possible.

The maximum number of special apprentices are limited to 20 for the system, divided equally between the locomotive and car departments and distributed at the principal points, in proportion to the force employed and the facilities for educating the apprentices involved.

The rates of pay will be increased annually instead of semi-annually as heretofore, as follows:

| | |
|---|---|
| First year | 62 cents per hr. |
| Second year | 65 cents per hr. |
| Third year | 68 cents per hr. |
| Fourth year | 72 cents per hr. |

Two hundred and ninety days actual service constitute a year. Overtime or sick leave is not included, except in special cases where the circumstances warrant modification, and only then after approval by the head of the mechanical department.

The greatest possible care is exercised in selecting special apprentices. A college education with diploma signifying completion of an approved course is not necessary, but is desirable. All applicants for the position of special apprentice should possess the qualifications for obtaining education that will enable them to absorb problems of a technical nature, and each applicant must be approved by the head of the mechanical department.

Special apprentices are not to be used on work other than what is outlined below, except in such cases as are authorized by the head of the mechanical department. The following schedules are outlined to guide in as practical a manner as possible, the diversity of service to which special apprentices should be assigned. Deviation is permitted as will best fit the ability of the individual apprentice and the facilities and circumstances obtaining:

SPECIAL APPRENTICE (STEAM TRAINING)

| | | |
|---|---|---|
| General machine work | 9 | mo. |
| General floor work | 12 | mo. |
| Special work | 15 | mo. |
| Minor supervisory work | 12 | mo. |

SPECIAL WORK

| | | |
|---|---|---|
| Enginehouse | 8 | mo. |
| Boiler shop | 2 | mo. |
| Blacksmiths shop | 1 | mo. |
| Powerhouse | $1\frac{1}{2}$ | mo. |
| Car shop and tender work | $2\frac{1}{2}$ | mo. |
| Total | 15 | mo. |

SPECIAL APPRENTICE (ELECTRICAL TRAINING)

| | | |
|---|---|---|
| Electrical engineers' office | 3 | mo. |
| General backshop work on electrical equipment, including control, relays, grids, etc. | 9 | mo. |
| General backshop machine work and erecting | 3 | mo. |
| Armature work | 3 | mo. |
| Batteries | 1 | mo. |
| Meters | 1 | mo. |
| Enginehouse (mech. and elec.) | 4 | mo. |
| Test track | 2 | mo. |
| Substation—operation and maintenance | 2 | mo. |
| Load dispatching and time spent with electrical instructor | 3 | mo. |
| Special assignments | 5 | mo. |
| Minor supervisory work | 12 | mo. |
| Total | 48 | mo. |

SPECIAL CAR DEPARTMENT APPRENTICE

| | | |
|---|---|---|
| Heavy repair track | $12\frac{3}{4}$ | mo. |
| Air-brake shop | $2\frac{1}{2}$ | mo. |
| Train yard | 1 | mo. |
| Coach yard | $1\frac{3}{4}$ | mo. |
| Wrecking outfit | $\frac{1}{2}$ | mo. |
| Wood mill | 1 | mo. |
| Blacksmith shop | 2 | mo. |
| Machine shop | 2 | mo. |
| Coach shop | $9\frac{1}{2}$ | mo. |
| Drafting room | 3 | mo. |
| Minor supervisory work | 12 | mo. |
| Total | 48 | mo. |

During the last 12 months, special apprentices are assigned in a minor supervisory capacity. It is intended by this assignment to develop the executive ability of special apprentices and give them an opportunity to prepare themselves for supervisory positions. It is the railroad's desire to arbitrarily make these specific assignments so that the special apprentice will direct and be responsible for not only his work, but that of such other employees as may be placed under his direct supervision. Definite assignments of this character are worked out as occasion requires.

## RAILROAD "L"

This railroad has had a course for special apprentices for about 20 years. It consists of a three-year course divided into six periods of six months each. Special apprentices must be graduates in mechanical engineering from schools of recognized standing, and the railroad prefers to have them enter its employ immediately after graduation. No applicants will be accepted after one year out of college. Each applicant must pass a physical examination similar to that required of enginemen and firemen, which is given by the company surgeon.

The first year of the course is as follows: Operating machines with one month assignment to special work for a master mechanic, mechanical superintendent, mechanical engineer, or the engineer of tests.

Second year: Floor, bench and erecting work, with one month of special work.

Third year: Two months boiler-shop work, two months freight-car shop, four months enginehouse, two months with a road foreman of engines, and two months inspecting locomotives.

The rates of pay are as follows:

| | |
|---|---|
| First six months | 53 cents per hr. |
| Second six months | $55\frac{1}{2}$ cents per hr. |
| Third six months | 58 cents per hr. |
| Fourth six months | $60\frac{1}{2}$ cents per hr. |
| Fifth six months | 63 cents per hr. |
| Sixth six months | $65\frac{1}{2}$ cents per hr. |

The following outside reading is recommended but not required: Locomotive and car folios of company standards, American Railway Association rules, company and Interstate Commerce Commission rules for the maintenance of locomotives and boilers, railroad operating rules, the *Railway Age*, own and use a good handbook such as Kent's, Machinery's, Marks', etc. A monthly letter is required from each special apprentice during his third year outlining the work he has done, with his comments, criticisms, and suggestions. Each special apprentice has the privilege of selecting the department in which he prefers to work on the completion of his course. Promotion depends entirely on individual ability. If two possess the same qualities or ability, promotion is then made according to seniority.

Promotion to supervisory positions in the shops or to permanent positions in the mechanical engineer's office, engineer of tests, or to apprentice instructor is made as soon as vacancies occur. Sometimes a promotion is made immediately, sometimes after one or two years, and sometimes never.

The following remarks were included at the end of the report on special training which was received from this road: "The course of training, while necessary for railroad work, appears too long when compared with the training in industrial plants. The immediate compensation is less, but the ultimate reward is fully as much."

## RAILROAD "M"

This railroad maintains a three-year special apprentice course. It consists essentially of three months on the erecting floor, two years in the machine shop, seven months on erecting and inspection work, and two months in the enginehouse.

The rates of pay are as follows:

| | |
|---|---|
| First six months | 51 cents per hr. |
| Second six months | 53 cents per hr. |
| Third six months | 55 cents per hr. |
| Fourth six months | 57 cents per hr. |
| Fifth six months | 59 cents per hr. |
| Sixth six months | 61 cents per hr. |

Seniority in line of promotion is not considered in the advancement of special apprentices. Ability, a combination of knowledge, experience, and the execution of common sense are the chief assets.

## RAILROAD "N"

Only graduates from technical schools of recognized standing are accepted as special apprentices by this road. No drafting-room work is included in the course of training, nor is the course confined entirely to work in the shop. Special apprentices are used largely as assistants in the compilation of test data and information, and work of similar nature. However, an opportunity is provided to obtain some of the regular apprentice training under an agreement with the shop crafts. Promotion is about the same as that for foremen in the majority of cases. A number, however, are assigned to work in the test department on completion of their course, or are assigned to duty as mechanics or to some other form of employment.

## RAILROAD "O"

This railroad has had a two-year special apprentice course in

operation for about two years. In this course, 145 days are spent on machine and bench work, divided as follows: 12 days on a planer, 12 days on a boring mill, 12 days on a shaper, 40 days on lathes, 10 days on a rod bench, 14 days on boiler mountings, 10 days at power plant, and 12 days on the link bench. A period of 145 days is spent on the erecting floor, divided up as follows: 14 days, shoes and wedges; 10 days, cylinders and frames; 13 days, guides and pistons; 14 days, driving boxes; 48 days, valves; 16 days, wheel gang; 14 days, cab work; 10 days, special work. (Total of 2320 shop hours constitutes the work of the first year.) Second Year—24 days on gas and electric welding; 74 days, enginehouse work of which 20 days are spent in general helping; 30 days running work and 24 days on air-brake and machinery inspection; 86 days are spent in the boiler shop of which 22 days are devoted to flues and arch tubes; 16 ash pans and grates; 12 days on the lay-out bench; and 36 days on firebox and boiler shell. Seventy-two days the special apprentice works in the freight-car shop, 12 of which are spent on trucks, couplers, and draft gears; 36 days on wood and body work; 24 days on steel-car work; (total of 2320 shop hours for the second year, including following road and special work; 14 days riding locomotives with the road foreman of engines and 20 days on special work).

The rates of pay are as follows:

| | |
|---|---|
| First six months | 50 cents per hr. |
| Second six months | 55 cents per hr. |
| Third six months | 60 cents per hr. |
| Fourth six months | 65 cents per hr. |

In the promotion of special apprentices, seniority counts for little. Experience is desired; ability the main factor. The special apprentice is not expected to handle supervisory work on the completion of his course, but receives consideration when vacancies arise. Graduates rate a mechanical assistant's pay at $175.00 per month. They fill vacancies as foremen, are assigned to the dynamometer car, etc. They also work on test, in the physical test laboratory and in the drafting room. Men working on these assignments are kept at this kind of work until a vacancy occurs in some supervisory position. These positions are considered in somewhat the light of a post-graduate special apprentice course, and is considered valuable experience.

## RAILROAD "P"

This railroad has two courses which are designated "Course A" and "Course B." "Course A" is a three-year course for college graduates and "Course B" is a five-year course for especially bright and studious regular apprentices. The following table shows the time spent in the various departments for both courses.

| | Time, A | Months. B |
|---|---|---|
| Machine shop | 10 | 18 |
| Erecting shop | 10 | 18 |
| Blacksmith shop | 4 | 6 |
| Drafting room | 4 | 6 |
| Boiler shop | 4 | 6 |
| Roundhouse | 4 | 6 |
| Total | 36 | 60 |

The salaries paid each six months to apprentices employed in the two courses are as follows:

| A | B |
|---|---|
| 55 cents per hr. | 30 cents per hr. |
| 55 cents per hr. | 32 cents per hr. |
| 58 cents per hr. | 34 cents per hr. |
| 58 cents per hr. | 36 cents per hr. |
| 61 cents per hr. | 38 cents per hr. |
| 61 cents per hr. | 40 cents per hr. |
| .......... | 42 cents per hr. |
| .......... | 44 cents per hr. |
| .......... | 46 cents per hr. |
| .......... | 48 cents per hr. |

The purpose of these courses is to promote graduates of either course to positions of responsibility as openings occur and the individual qualifies for the position. At the present time, this road has seven graduates, two of whom are now serving as enginehouse foremen and five are awaiting promotion. The management pursues the policy that some men are especially adapted to certain lines of work and would be failures in others. It endeavors to place men where they are best suited, both from the standpoint of the company and for themselves.

## RAILROAD "Q"

The special apprentice course on this road is under the direct supervision of the shop superintendent and master mechanic and is directed by the superintendent of motive power. The duration of the apprenticeship is three years. The special apprentice receives 50 cents per hour at the start with an increase of 2 cents per hour every six months. There is no definitely outlined course.

## RAILROAD "R"

The special apprentice course on this road is under the supervision of the master mechanic. The course has not definitely been outlined but is under the direction of the superintendent of machinery. The duration of the apprenticeship is three years. The rates of pay for the special apprentice is not less than that for helper apprentices for whom the rate is 51 cents per hour.

## RAILROAD "S"

Special apprentices employed by this road must be graduates in railway mechanical engineering from a recognized technical university. Each special apprentice attends the regular apprentice schools three hours a week where they study locomotive and car design, thermodynamics relative to locomotive boiler and steam distribution, standard practice and work of a special nature. They are also required to submit a report each month on subjects such as the following: Scheduling, track stresses, locomotive boosters, feedwater heaters, superheaters, valve gears, etc. The following shows the time spent by the special apprentice on various machines and in various departments.

| | |
|---|---|
| Drill press | 1 mo. |
| Shaper | 1 mo. |
| Frames and cylinders | 2 mo. |
| Bolt lathes | 3 mo. |
| Engine lathes | 3 mo. |
| Boring mill | 2 mo. |
| Planers | 2 mo. |
| Cabs and steam pipes | 2 mo. |
| Guides | 1 mo. |
| Shoes and wedges | 2 mo. |
| Air room | 2 mo. |
| Tool room (manufacture) | 1 mo. |
| Motion bench | 1 mo. |
| Valve gang | 2 mo. |
| Boiler shop | 2 mo. |
| Electrical shop | 1 mo. |
| Enginehouse | 3 mo. |
| Freight-car shop | 2 mo. |
| Engine inspector | 1 mo. |
| Air instruction car | 2 mo. |
| Total | 36 mo. |

The following are the salaries paid special apprentices for each six months.

| | |
|---|---|
| First six months | 49 cents |
| Second six months | $51^1/_2$ cents |
| Third six months | 55 cents |
| Fourth six months | $57^1/_2$ cents |
| Fifth six months | 60 cents |
| Sixth six months | $62^1/_2$ cents |

The school schedule for special apprentices on this road is outlined in such a way as to encourage special apprentices to read and study on such subjects as railway economics, locomotive design, car design, locomotive and car performance, combustion, locomotive and car appliances, labor turnover, foremanship, conservation of fuel, materials, etc. The history of transportation, railway organization and finance, relations between various railway departments, locomotive testing and the testing of materials and devices are also included in a recommended course of study for special apprentices.

At the present time this railroad has four special apprentices on its lines and have graduated none since the organization of its present training system. It is greatly interested, however, in this venture and what it has accomplished so far, the road reports, is indicative of some very fine results.

## RAILROAD "T"

Applicants for special apprenticeship on this road must be graduates of colleges of recognized standing in mechanical engineering

or may be first employed during the summer months on the completion of two years of collegiate work in the course mentioned. In the latter case, employment is contingent upon the special apprentice regularly completing his collegiate work.

Special apprentices are not required to attend the regular apprentice school and do the regular assignment of outside work. During their apprenticeship, however, special apprentices are given from time to time outside work such as studies of A.R.A. rules, safety appliance rules, Federal locomotive inspection rules, etc. However, a study is now being made with a view toward drawing up a required course of outside study and reading. This has not been completed but will, in all probability, be based on the following subjects and books: The Railroad Standard Practice Folio; The Railroads Safety First Manual; A.R.A. Rules of Interchange; A.R.A. Safety Appliance Rules; U. S. Government Locomotive Inspection Rules; Locomotive Cyclopedia; Car Builders Cyclopedia; The Locomotive Up-to-date, by Chas. L. McShane; Railroad Freight Transportation, by L. F. Loree and work in a regular apprentice school studying questions on all phases of shop work.

The library of the apprentice school is quite complete with books containing shop administration, railroad accounting, locomotive and car design and repair, etc. Special apprentices are encouraged to make use of the library. Special apprenticeship is based on four periods of 1160 hrs. each with the rates of pay as follows:

| | |
|---|---|
| First period | 50 cents per hr. |
| Second period | 55 cents per hr. |
| Third period | 60 cents per hr. |
| Fourth period | 65 cents per hr. |

The routing of special apprentices to the shop does not follow a regular schedule in sequence. Freight car work may precede boiler shop work but when an apprentice is assigned to one shop, he must complete that before going to another. For example, an apprentice half-way through his freight-car work would not be sent to the engine-house and then back to the freight repair yard. The job assignments of special apprentices are as follows:

Job Assignments

First Year

| | | |
|---|---|---|
| Machines and benches | | 145 days |
| Planer | 12 days | |
| Boring mill | 12 days | |
| Shaper | 10 days | |
| Lathes | 40 days | |
| Rod bench | 10 days | |
| Link bench | 12 days | |
| Lubricators, injectors, etc. | 14 days | |
| Tool room | 25 days | |
| Power plant | 10 days | |
| Erecting floor | | 145 days |
| Shoes and wedges | 14 days | |
| Cylinders and frames | 16 days | |
| Guides and pistons | 13 days | |
| Driving boxes | 14 days | |
| Valves | 48 days | |
| Wheel gang | 16 days | |
| Boiler mountings | 14 days | |
| Special work | 10 days | |

Second Year

| | | |
|---|---|---|
| Gas and electric welding | | 24 days |
| Roundhouse | | 74 days |
| General helping | 20 days | |
| Running work | 30 days | |
| Air and machinery inspection | 24 days | |
| Boiler shop | | 86 days |
| Flues and tubes | 22 days | |
| Ash pan and grates | 16 days | |
| Layout bench | 12 days | |
| Firebox and boiler shell | 36 days | |
| Freight car shop | | 72 days |
| Trucks, couplers, draft gears | 12 days | |
| Wood body work | 35 days | |
| Steel work | 24 days | |
| Riding engines with traveling engineers | | 14 days |
| Special work | | 20 days |

This railroad reports that seniority plays a comparatively little part in the selection of men for minor supervisory positions. Experience and superiority take preference. A special apprentice course takes but two years and it does not expect a graduate to be able to assume a major supervisory position immediately upon graduation. In order to take care of graduate special apprentices, plans have been approved to create positions to be known as mechanical assistants who report to the superintendent of machinery. As mechanical assistants they will be used as "pinch hitters" where-ever additional help is needed for short periods, such as on the dynamometer car, in the mechanical engineer's office, test department or filling supervisory positions temporarily. Mechanical assistants will also be assigned to special work and investigations by the superintendent of machinery. This position will pay $175 per month. The management believes that this method will be of particular benefit to the special apprentices as they will profit by the association and supervision of officials and will give him considerable additional experience. It is intended that graduate special apprentices will work as mechanical assistants until there is an opening which the management believes the individual is capable of filling.

## RAILROAD "U"

The special apprentice employed on this railroad must have completed a technical course along mechanical lines at a recognized technical school and must meet the road requirements for the employment of regular mechanical apprentices which are as follows: Age limit of the applicant is between 18 and 26 years. They must pass a physical examination and serve three years of 290 days in each calendar year.

During the special apprentice course they must study the course prescribed by the Railway Educational Bureau, Omaha, Neb., which deals with technical mechanical problems associated with railway mechanical engineers and supervision. Each special apprentice receives training in the various departments in the different classes of work in the various crafts in the maintenance of equipment departments. They are moved from place to place or required to work in any class of work at the discretion of the officer in charge. The rates paid special apprentices during the different periods of their apprenticeship are as follows:

| | |
|---|---|
| First period | 49 cents per hr. |
| Second period | 51 cents per hr. |
| Third period | 53 cents per hr. |
| Fourth period | 55 cents per hr. |
| Fifth period | 57 cents per hr. |
| Sixth period | 59 cents per hr. |

On completion of their course, special apprentices are placed in positions where their past individual performance has indicated their ability and aptitude are best suited. These positions are selected with the primary object of acquiring further experience in railroad work and they are kept in that position until their work demonstrates that they are ready for promotion to some supervisory capacity.

## RAILWAY-SUPPLY COMPANY "V"

The object of this course is to prepare college graduates for work in the engineering department and for mechanical positions in the field when there are openings for such.

This special course is limited to a period of six months and is purely preparatory, the work covered during this time being a study of the design, construction and operation of numerous typical air brake equipments. A typical daily program is as follows:

7:15 to 10:45 A.M.—Study period
10:45 to 11:00 A.M.—Physical exercise
11:00 to 12:00 A.M.—Lecture and discussion
12:45 to 4:45 P.M.—Practical shop work.

A special class room is provided for the study period, during which period standard instruction pamphlets are used as textbooks. A set of questions covering each pamphlet must be answered in writing, which answers are then checked by other students and a final check made by the department head. Errors must be corrected after a discussion and a clear understanding of the question.

During the lecture and discussion hour lantern slides are used, and members of the engineering department and other departments of the organization, give talks to the class on the subject being studied, or other allied subjects which may pertain to the organization of the company. These subjects are of special interest and value to the student in his work later.

In the afternoon practical shop work is done in a place especially assigned for this work, it being impracticable to work in our regular production departments, as all this work is on a piece work basis. The work performed is to secure from the plant unfinished parts comprising the equipment being studied, which parts must be finished and assembled in the same manner in which they would be applied

to locomotives or cars, thereby giving the student practical knowledge of the device as studied, both from a manufacturing, assembling, installation, and operation standpoint.

As a general rule, the man is assigned work, under supervision in the test department, unless he is interested in design work, in which event he is assigned to the drawing room. As minor executive positions in the engineering department or openings in our field organization become available, selection is made of the man who has demonstrated, by his work and attitude, peculiar fitness for the position.

## Discussion

A. G. TRUMBULL.[11] The paper, which has been prepared by the Sub-Committee on Professional Service of the Railroad Division, presents to the young graduate engineer a very fair statement of the opportunities existing for him in the railroad and its allied field, the supply industry. Of necessity, a report of this character must present pertinent facts, leaving to the individual the application of those facts to his own particular problem.

In this age of intense specialization the choice of a field of endeavor is second only to the choice of a vocation, and requires equally serious consideration. Disappointment not infrequently results from a choice dictated by wholly irrelevant circumstances. Unquestionably, the colleges and technical schools can be of great assistance to their graduate engineers in directing them toward a field of effort appropriate to their particular abilities and individual characteristics. Based on personal experience, as well as contact with young engineers entering the railroad field, the writer has been impressed by what has often appeared to have been an unhappy choice, which well-informed advice might have avoided. No one should be as well qualified to give this advice as the responsible heads of engineering colleges. Vocational departments of these colleges, under the sympathetic supervision of well-rounded executives, should prove of advantage alike to industry, to the colleges, and to their graduate engineers.

There are numerous instances in the experience of every executive in which young men are found to be ill adapted to the work which they have undertaken, due frequently to unhappy parental advice. It is perhaps natural to assume that the youthful pride of the family, who is discovered taking the clock apart, is destined to be a mechanical genius, whereas a disinterested opinion would properly classify this as a simple manifestation of the inquisitive instinct. Many unfortunate errors of choice would be avoided by the application of simple principles of analysis. This may be readily understood in its application to railroads as differentiated from other mechanical pursuits. Of necessity, the problems of maintenance have to do with large units of equipment, and there are obvious instances where individuals are unfitted by temperament and inclination for work of this nature. With equal ability they might succeed in the automobile industry and fail on a railroad, even though their talents were applied with equal industry. Assuming, however, that a choice has been appropriately made, there remain in the railroad field several directions in which mechanical training may be applied.

The Army presents an analogy to the railroads, in that it consists of the line and the staff. The higher officers are generally selected from the line, which limits the opportunities for the staff. While this rule is not as inclusive with the railroads as the Army, it is generally applied. The reason for this, in the case of the railroads, is that they are engaged in the transportation business. Matters relating to equipment, whether of design, maintenance, or operation, and those relating to roadway and structures, are collateral to the general function of the industry. It is natural, therefore, that the line of promotion should lie in the direction of the chief function. This is the reason for the fact that so few mechanical officers are found in the higher executive positions of the operating department. It should not be understood that the avenue of promotion to mechanical-department officers is closed, but it is the exceptionally well-grounded and all-around man who becomes a transportation-department officer.

In the mechanical department there are two fields which the graduate engineer may enter. Primarily, the mechanical department is responsible for maintenance of equipment, and it is maintenance which involves the greatest expense in this department. Here there is the same analogy as in the operating department, i.e., promotion is generally through the line, which is concerned with the maintenance, rather than through the staff, which has to do with engineering.

Having selected railroad work as a vocation, it is therefore important that an early decision be reached as to the particular branch to be followed, since, if the young engineer aspires to become the head of the mechanical department, his opportunities or advancement are greater if he selects shop operation in preference to engineering. On the other hand, if his inclinations are for the purely technical aspects of the work, he is likely to find the shop work irksome and insufficiently interesting to warrant the application, industry, and persistence necessary to advancement.

The report wisely refrains from presenting any rules designed to promote success in the railroad or supply fields. The popular newspapers and magazines are filled with interviews and biographies of prominent captains of industry and leaders of business, most of which, through analysis of the habits of the individual, attempt to indicate qualities which have most contributed to the outstanding success of the object of these articles.

It is a fundamental biological fact that the same success in any field would not be attained by two individuals, even under the same conditions, for the reason that their reactions to a given set of circumstances are entirely different; moreover, the circumstances are never duplicated. This raises the important and ever-debatable question as to the influence of opportunity upon success. Our recent president, Mr. Charles M. Schwab, modestly states that opportunity had much to do with his career, and adds that in his opinion there are any number of men who, having had the same opportunities as he, would have been even more successful than he is generally regarded. It may be questioned if this view promotes a hopeful outlook for the obscure engineer of even average ability. Probably he would prefer to regard individual qualities as of greater importance than fortuitous circumstances. It is quite evident, however, that opportunity does have a large influence upon individual careers, and the difficulty in creating those opportunities is, the writer believes increased by the growth of what has come to be termed "Big Business." But the situation in this report is not less favorable with the railroads than elsewhere.

It is interesting, however, to note those qualities which are considered essential to success in different lines of endeavor. For example, one of the supply companies prescribed these qualifications:

1 Ability to handle men
2 Originality of thought
3 Pleasing personality
4 Initiative.

Probably the packing business is as widely separated as any from the railroad or railroad-supply field. It is interesting to note the views of the head of the personnel department of Armour & Company as to the qualities and abilities which weigh in the rating of supervisors. These are:

[11] Chief Mechanical Engineer, Erie R.R. Co., New York, N. Y. Mem. A.S.M.E.

1 Personal qualities
2 Intelligence
3 Physical qualities
4 Leadership
5 Trade knowledge.

The latter are more general in character and offer a reasonable basis for weighing relative individual abilities. There is nothing to indicate how the maximum of these various qualities may be acquired, but they do suggest the advisability, if not the necessity, of frequently looking into the glass to see how one's general characteristics are contributing to these qualities.

Not all can attain the heights of the profession. For most of us, in the maturity of experience, the fancies of youth will yet have neither form nor substance, but there will be satisfaction if the ideals of the profession are maintained. Moreover it is reasonably certain that each individual will have contributed some share to the advancement of engineering and the mechanic arts. With this, too, a reasonable economic return will have been realized.

L. L. Park.[12] In addition to the points already stressed in the report, there is the problem of bringing the "rank and file" in the motive-power and car departments up to the higher demands of modern equipment. With the increased complexity of the equipment comes not only the need for technically trained leadership but for a better informed group of subordinates, trained to meet the more difficult problems arising out of the new railway policies.

To the technically trained man in the railroad field there is presented the opportunity for aiding those in the ranks who have ability for self-development, to prepare themselves for more effective work. Among the ways in which this service might be rendered are the following:

1 The encouraging and directing of study in technical subjects
2 The application of such technical study to the needs of the mechanical departments
3 Aid in acquiring the art of analysis in problems of improvement in locomotive or car parts to determine the probable cause of failure and means of remedy
4 The development of sane ideas in matters of design.

Too often the men who are eligible for advancement in the mechanical departments are poorly equipped for adequately handling technical matters arising out of railroad operation, and there would seem to be a distinct advantage in having in responsible positions men whose training qualifies them to properly aid in building up the "second line of defense" in the maintenance and improvement of mechanical equipment.

[12] American Locomotive Co., Schenectady, N. Y.

R. S. McConnell.[13] This report of the Committee on Professional Service, Railroad Division, is presented as a demonstration of the average experience that may be expected by the mechanical engineer in these industries.

It is the hope of the Committee that graduates in mechanical engineering, when debating the choice of a career, will give thoughtful consideration to the railroads and allied industries, which, it is believed, present opportunities equal to those offered in any other fields.

The value of the mechanical engineer to railroad and supply organizations, and the opportunities afforded him in these fields of endeavor, are receiving more attention today than at any time in the past. That this is the age of engineering is wholly true of these industries, and the services of competent mechanical engineers are in demand in all lines of operation, maintenance, and sales.

Education and training place in the head and hands of the student the tools with which to work, and reveal to him the purposes for which those tools are intended. The use which the worker makes of that which he has been taught determines how far he will go in his chosen career. Unless we make ourselves useful, we cannot expect the world to pay much attention to us.

It is easy to criticize slow progress; so, if progress appears not to conform to preconceived ideas, the reasons for such failures must not be mistaken. That the fault will not be found in a lack of opportunities for advance is quite as true of the railroad and supply industries as of any other activities.

When honorary membership in the Society was recently conferred upon the distinguished French chemist, Prof. Henry le Chatelier, the *A.S.M.E. News* stated that he remarked in his address of acceptance that "the application of common sense to industry is a distinct contribution of the United States to the present era."

Given the appropriate education and training, that statement of Professor le Chatelier's contains the element for successful achievement within the railroad and supply industries as in any other field of activity.

# Can Accident Prevention Be Reduced to a Science?

By THOMAS H. CARROW,[1] PHILADELPHIA, PA.

*The author concludes that accident prevention can be reduced to a science. This conclusion is based on an analysis of the causes of accidents, which shows that not more than ten per cent are due to misadventure and therefore unpreventable, and an analysis of the human factor to which eighty-five per cent of all accidents are attributable. He stresses the need of complete accident records and of educating supervisory responsibility in safety.*

THE WORD "science" as used in this outline is intended to mean specific ways and means that have been or may be successfully used in the prevention of accidents, particularly with respect to injuries sustained by employees engaged in the railroad, construction, manufacturing, or other kinds of business.

### Number and Cost of Accidents

The reason for and the extent of the effort necessary to prevent accidents in any industry as a whole or in any given unit of an industry are determined primarily by the number, result, and cost of accidents and the advantages to be derived from such effort.

The number, result, and cost may be obtained by an analysis of reports of accidents and other records. Cost includes not only payments on account of compensation, claims, and damage to property, but also expenses due to:

1 Interruption and delay in operation
2 Investigation and reports of accidents
3 Loss of good will
4 Disarrangement of working forces and delay to work
5 Cost of breaking in new men (estimated at $50 to $250 per man).

### Advantages of Accident Prevention

The following statements suggest the possible advantages to be derived from the prevention of accidents:

1 Conserves life and limb
2 Effects economy in operation
3 Increases the popularity of the business
4 Makes the business a more attractive investment
5 Is a good advertisement for efficient management
6 Forestalls burdensome legislation
7 Obviates embarrassment of executive officers
8 Minimizes "hazard of employment" as a factor in wages
9 Does not slow up work or production
10 The public ultimately demands a reasonable standard of safety not voluntarily provided.

### Causes of Accidents, and Preventive Measures

Having determined to put the machinery of accident prevention in motion, the next step consists of an analysis of the causes of accidents and a determination of practical preventive measures, the following being a statement of general causes and the percentage of the total number attributable to each cause, and preventive measures which may be amplified to suit specific conditions:

*Physical Conditions*

| Causes of Accidents | | Preventive Measures |
|---|---|---|
| 1 Unsafe design and construction | 5 per cent | 1 Change in design and improved construction |
| 2 Lack of physical safeguards | | 2 Installation of necessary safeguards |
| 3 Defective material and equipment | | 3 Efficient inspection and maintenance |
| 4 Litter in walk-ways, or material unsafely piled or placed | | 4 Good housekeeping |
| 5 Other physical hazards | | 5 Miscellaneous |

*Human Factor and Misadventure*

| | | |
|---|---|---|
| 6 Violation of rules and other forms of negligence | 10 per cent | 6 Proper training, supervision and discipline |
| 7 Carelessness, thoughtlessness, indifference and ignorance | 70 per cent | 7 Safety organization, education, persuasion and cooperation |
| 8 Physical and mental unfitness | 5 per cent | 8 Proper selection and placing of employees first aid and medical attention |
| 9 Misadventure | 10 per cent | 9 Unpreventable |
| Total from all causes | 100 per cent | |

Note: The percentage of accidents due to each cause varies with different kinds of business and with progress in accident prevention.

### The Individual Worker

From the analysis of the causes of accidents it is seen that 85 per cent of all accidents are attributable to the human factor. It is therefore in line with engineering principles to analyze the nature of the genus *Homo* to determine inherent tendencies to accident and the possibility of counteracting these tendencies. An outline for such an analysis follows:

*The Make-Up of a Man*

| Physical | Mental | Moral |
|---|---|---|
| Positive: | Positive: | Positive: |
| Health | Understanding | Appreciation of right |
| Strength | Judgment | Desire to do right |
| Skill | Reason | Dissatisfaction with wrong |
| Quickness of action | Perception | |
| Eyesight | Apprehension | |
| Hearing | | |
| Negative: | Negative: | Negative: |
| Disease | Natural limitations | Indifference |
| Weakness | Forgetfulness | Carelessness |
| Clumsiness | Dullness | Perversity |
| Awkwardness | | Recklessness |
| Laziness | | Don't care |
| Defective eyesight | | Lack of precaution |
| Defective hearing | | |

[1] Superintendent of Safety, The Pennsylvania Railroad Co.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers.

The extent to which the positive side of the individual is developed represents the degree of success achieved in overcoming the effect of the negative side, that is, the tendency toward accident. Some individuals pass a whole lifetime without serious injury, while others frequently sustain injury, as a complete accident record covering a number of years in any business will show.

### Safety Rules

In every line of work rules are necessary, accident prevention being no exception. Safety rules to be effective must cover both *prohibitions* and *requirements*. Employees in each line of work must be prohibited from doing "things" which may cause accidents, and they must be required to do the "things" that are necessary to insure safety. A report of a preventable accident is record of failure in the performance of duty, either on the part of the man injured, his supervisor, or both. It follows, therefore, that the formulation and enforcement of safety rules suitable to each business is a necessary preventive measure. The safety rules for each industry or business are of necessity peculiar to that industry or business, and should specify the "things" that are prohibited and those that are required.

Violations of prohibitory rules are easily detected. Generally speaking, however, the requirement rules have not been fully developed, and supervisory forces are therefore not educated to enforce them. They are, nevertheless, the more important of the two.

### Accident Record

It is a fact that some accidents are beyond the control of both men and management, while in many instances it is impossible to determine whether the responsibility does or does not lie with the injured. But a cumulative accident record will in time disclose whether an injured man is unduly susceptible to injury in the specific line of work in which he may be engaged. Hence the necessity for complete and continuous accident records.

As bearing on this point, the following accident record of eight men is quoted:

| | |
|---|---|
| Car repairman injured | 3 times in 26 years of service |
| Car repairman injured | 18 times in 9 years of service |
| Machinist injured | 0 times in 31 years of service |
| Machinist injured | 31 times in 23 years of service |
| Freight conductor injured | 1 time in 26 years of service |
| Freight conductor injured | 11 times in 20 years of service |
| Locomotive engineer injured | 0 times in 26 years of service |
| Locomotive engineer injured | 7 times in 33 years of service |

### Educating Supervisory Forces in Safety

If the first step in accident prevention is a matter of supervisory responsibility, which it is generally conceded to be, it is the duty of the management to see that the supervisory forces properly understand how this responsibility should be met, and until a system of accident prevention has been developed along scientific lines, it will not be possible to accomplish maximum results. On the other hand, when accident prevention has been developed along scientific lines, somewhat as suggested in this outline, there is no reason why the management of any business may not expect and determine to a nicety whether or not accidents are being prevented to the fullest extent.

### Reductions in Railroad Accidents

The following are the frequency rates of accidents to railroad employees on duty as reported by the Interstate Commerce Commission, 1923 to date:

| Year | Casualties per million man-hours |
|---|---|
| 1923 | 30.9 |
| 1924 | 27.3 |
| 1925 | 26.1 |
| 1926 | 23.9 |
| 1927 (6 months) | 20.7 |

The progressive improvement indicated, which is very much more impressive with respect to individual railroads than with all railroads taken as a whole, may be attributed to the application of the principles outlined above.

### Cost of Accident Prevention

The cost of accident prevention in its most highly developed form is comparatively low while the returns therefrom are substantial. The experience of a trunk-line railroad, shown below, will prove this:

| Year | Cost of injuries to employees |
|---|---|
| 1923 | $327,656.54 |
| 1924 | 185,297.17 |
| 1925 | 133,057.42 |
| 1926 | 82,470.24 |

### Conclusion

Can accident prevention be reduced to a science? In the light of the foregoing outline, which is based upon exhaustive analysis, the author believes it can.

## Discussion

M. J. T. Conway.[2] Mr. Carrow's paper deals with a timely topic and is of interest not only to the railroad companies but to every industry. He is right in his argument that the supervisory forces must realize their responsibilities as the first step in accident prevention and control. The writer believes that the greatest factor in the cause for accident prevention is the foreman, the first and last man in the supervisory ranks. He is the one man who must be thoroughly sold to the safety-first idea before safety can be efficiently practiced by the rank and file. Indifference on the part of the foreman will surely have its bad effect on those he supervises, and time spent on getting safety thoroughly soaked into the mind of the foreman is the best investment that can be made in an accident-prevention campaign in any industry.

At the plant where the writer is employed, which has the typical hazards of all rolling-mill plants, we have just completed a year's safety campaign put on through the foremen of the plant, and the results have been worth while. The lost-time accidents together with the minor accidents, have been cut down 50 per cent.

The number of trained first-aid men in an organization is fairly indicative of that organization's safety record. It has been the writer's experience that a first-aid man is usually a safety man who preaches safety, a preventive rather than a cure, and the cost of training these men in first-aid work is more than repaid by the cleaner safety records of the organization to which they belong.

William Elmer.[3] The average engineer is fairly familiar with the fact that the railroads of the nation are extremely inter-

[2] Fuel Engineer, Lukens Steel Co., Coatesville, Pa. Mem. A.S.M.E.

[3] Special Engineer, Pennsylvania R.R. Co., Philadelphia, Pa. Mem. A.S.M.E.

ested in the reduction of accidents. They have set a goal for a five-year program of a reduction of 35 per cent in the number of accidents on railroads. They have made remarkable progress toward that goal, and in looking over some statistics it is marvelous to see how some railroads are able to operate with such a small number of accidents, and how far others are behind those ideal performances.

The statistics are usually prepared on the basis of the number of accidents per million man-hours, and some of the railroad systems have reached the point where there are decidedly less than ten casualties per million man-hours. The Union Pacific, for instance, has $3^1/_2$ casualties per million man-hours. The country as a whole averages about 19.

In the train accidents per million locomotive-miles, the Burlington Route and the Great Northern Railroad are both $3^1/_2$ or less, whereas the average for the country is 11. Attention paid to these matters is therefore sure to produce the desired results.

Eliot Sumner.[4] It is possible for a shop force to become over-zealous in the matter of accident records. For instance: A certain shop posted up each month the number of accidents causing loss of time. If an injured employee was attended in the first-aid room and went back to work, no time was lost. An inspection one day disclosed a man reading a newspaper in the locker room. An inquiry developed the information that the man had been injured and was not able to resume his normal duties. However, they thought that he would be in a day or two, so they said: "You come to work anyway, and as soon as you are able to do your regular work we will put you on it." In the meantime he was allowed to read the newspaper, so it was not reported as a lost-time accident and gave a clean record for the month. This shows what may be done with paper figures when they are not carefully policed.

[4] Superintendent of Motive Power, Pennsylvania R.R. Co., New York, N. Y. Mem. A.S.M.E.

The Author. While the case cited by Mr. Sumner is an indication of inefficient management, it is nevertheless a fact that hundreds of men are assigned to other than their regular work, which work they perform efficiently and satisfactorily.

This point is illustrated by an observation made by the general manager of a certain plant to the effect that it was easier for a foreman to send a man home than it was for him to find suitable work for him when he was unable to perform his regular duties. Furthermore, an injured man at some work other than his regular job is better off than when he is loafing.

# High Steam Pressures in Locomotive Cylinders

By LAWFORD H. FRY,[1] BURNHAM, PA.

*In this paper the author attempts an extended survey of the efficiencies obtainable with various steam pressures, and examines the effect of the ratio of expansion on the efficiency. The Rankine cycle, it is pointed out, does not offer a satisfactory basis of comparison for the locomotive; therefore a modification is suggested, known throughout the paper as the "locomotive cycle," and all calculations of the paper are based on this cycle. Changes in boilers to permit operation at high pressures and temperatures are discussed, and it is pointed out that such a boiler would probably require some form of water-tube firebox. Detailed computations and comparisons of theoretical indicator diagrams are made, and the "locomotive cycle" is applied to various admission and release pressures. It is concluded that it is possible to secure a considerable increase in the thermal efficiency of the cylinders by increasing the boiler pressure. The use of three cylinders, one operating on high pressure and two low, makes compounding a very simple matter, permitting the greatest return to be received from the high pressures. For the present, however, it is not felt to be expedient to use boiler pressures much in excess of 450 lb. per sq. in. gage.*

A RECENT paper by Schmidt and Snodgrass[2] gives some information as to experiments which are being made with high steam pressures for locomotives. The theoretical efficiencies obtainable with various pressures are compared briefly, the comparisons being based on the Rankine cycle.

The present paper attempts a somewhat more extended survey of the efficiency obtainable with various steam pressures, and examines the effect of the ratio of expansion on the efficiency. For this purpose the Rankine cycle does not offer a satisfactory basis of comparison, and a modification suggested by the author in discussing the Schmidt and Snodgrass paper is used. This is referred to hereafter as the "locomotive cycle." It assumes that the steam is admitted to the cylinder at constant pressure and temperature, and then, after cut-off, is expanded adiabatically to the release pressure corresponding to the ratio of expansion desired. Release is assumed to take place at the end of the stroke, and the pressure is assumed to fall immediately to the back pressure against which exhaust takes place. The cylinder is assumed to have no clearance.

Fig. 1 illustrates diagrams of this locomotive cycle in comparison with a Rankine-cycle diagram. *ABCDA* is the Rankine diagram for admission at 350 lb. per sq. in., adiabatic expansion to 25 lb. per sq. in., and exhaust at 25 lb. per sq. in. *ABEFDA* is a diagram of the locomotive cycle with admission at 350 lb. per sq. in., adiabatic expansion to a release pressure of 50 lb. per sq. in., and exhaust at 25 lb. per sq. in. *ABNPDA* and *ABQRDA* are locomotive-cycle diagrams with conditions similar to *ABEFDA*, except that the release pressures are respectively 125 and 200 lb. per sq. in. *ABTDA* is a locomotive-cycle diagram with full-stroke cut-off, the release pressure being the same as the admission pressure, 350 lb. per sq. in. Methods of plotting these diagrams, and results obtained by computing and comparing the thermal efficiencies, are given below. Before approaching these problems it is well to consider the values to be assumed for the steam temperature on admission, and for the exhaust pressure.

The present study of high steam pressures is directed to locomotive practice only, and is based on the assumption that no fundamental change in locomotive design is made. It is assumed that if the steam pressure is increased no changes will be made in the locomotive design except those necessary to enable the steam at the higher pressure to be produced safely and to be utilized efficiently. For the locomotive boiler a pressure of 250 lb. per sq. in. is usually taken to be about the maximum that can be carried with the conventional firebox with its sheets supported by staybolts. The use of the higher pressures with which the paper is concerned will require some form of water-tube firebox, but will not force any other vital change. Consequently there seems to be no reason to assume any great change in steam temperatures. At present steam temperatures range normally between 600 and 700 deg. fahr., according to working conditions. In the calculations which follow the steam is assumed to have a temperature of 650 deg. fahr. during admission to the cylinder, irrespective of the pressure.

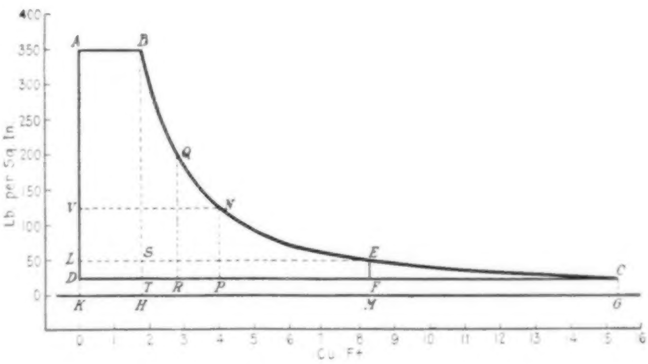

Fig. 1 Theoretical Indicator Diagram for Adiabatic Expansion of 1 Lb. of Steam From 350 Lb. per Sq. In. Absolute and 650 Deg. Fahr.

Another factor stabilized in the locomotive is the minimum exhaust pressure. Exhaust must be made to the atmosphere, and therefore the least back pressure must be higher than atmospheric. In actual practice the exhaust pressure varies between 20 and 50 lb. per sq. in. absolute, according to the rate at which steam is passed through the cylinders. For present purposes the exhaust pressure for the theoretical indicator diagrams which are computed is assumed to be in all cases 25 lb. per sq. in. absolute.

We now take up in detail computation and comparison of theoretical indicator diagrams, and apply the locomotive cycle to various admission and release pressures. In what follows it is convenient to measure all pressures in pounds per square inch absolute. The properties of steam used are taken from Keenan's "Progress Report on the Development of Steam Charts and Tables from the Harvard Experiments."[3] In all of the theoretical indicator diagrams the temperature of the steam on admission is taken as 650 deg. fahr. for all pressures, and the back pressure during exhaust is taken as 25 lb. per sq. in.

Fig. 1 shows the adiabatic expansion of one pound of steam from a pressure of 350 lb. per sq. in. and 650 deg. fahr. Ad-

[2] The Use of High Steam Pressure in Locomotives, E. C. Schmidt and J. M. Snodgrass, *Mechanical Engineering*, Mid-November, 1926, p. 1195.

Contributed by the Railroad Division and presented at the Spring Meeting, White Sulphur Springs, W. Va., May 23 to 26, 1927, of The American Society of Mechanical Engineers.

[3] *Mechanical Engineering*, February, 1926, p. 144.

mission of one pound of steam, from *A* to *B* at full pressure and temperature, gives a volume of 1.80 cu. ft. The external work done by the steam during admission is $144 \times 1.80 \times 350$ ft-lb., which is the equivalent of $0.1852 \times 1.80 \times 350 = 117$ B.t.u.

Now the steam tables show that at 350 lb. per sq. in. and 650 deg. fahr. the total heat energy per pound of steam is 1338 B.t.u. Deducting from this the external work as above, leaves 1221 B.t.u. as the internal energy of the steam at cut-off. The curve *BEC* has been determined from the steam tables to show the drop in pressure and increase in volume during expansion. At *C*, with a pressure of 25 lb. per sq. in. absolute, the volume is found to be 15.3 cu. ft., and the quality 0.938 per cent. Under these conditions the steam has a total heat energy of 1102 B.t.u. with an external work value of $0.1852 \times 15.3 \times 25 = 70$ B.t.u., giving an internal energy of 1032 B.t.u. As expansion is assumed adiabatic no heat is received by the steam and all the heat given up during expansion is transformed into work. Therefore the external work done during expansion is $1221 - 1033 = 188$ B.t.u. To complete the cycle the steam must be exhausted. This is assumed to take place at a constant back pressure of 25 lb. per sq. in., giving the line *CD*. The work lost is $0.1852 \times 25 \times 15.3 = 70$ B.t.u. The net work done by the steam during the cycle is therefore as follows:

| | |
|---|---|
| During admission | 117 B.t.u. |
| During expansion | 188 B.t u. |
| Total | 305 B.t.u. |
| Lost during exhaust | 70 B.t.u. |
| Net work of cycle | 235 B.t.u. |

This sequence of operations, admission at constant pressure, adiabatic expansion to a lower pressure, and exhaust at that pressure, constitutes the Rankine cycle. The amount of work developed can be found by a simpler method of calculation than that used above. It is only necessary to note that the steam has on admission a total energy of 1338 B.t.u. and on exhaust 1103 B.t.u., and that as expansion takes place adiabatically, without heat transfer between steam and cylinder, the difference, $1338 - 1103 = 235$ B.t.u., must be the energy transformed into work.

An indicator diagram constructed on the Rankine cycle gives the maximum amount of work which it is theoretically possible to extract from steam working between a given admission and a given exhaust pressure. It has, however, some disadvantages for locomotive work. For example, the steam in a locomotive cylinder is never expanded all the way down to the exhaust pressure. This condition may be approximated with a short cut-off and long expansion, but with a low ratio of expansion the Rankine-cycle diagram is not in any way representative of the actual diagram. With an admission pressure of 350 lb. per sq. in. and expansion to 125 lb. per sq. in. the Rankine-cycle diagram would be *ABNVA*, Fig. 1, which owing to the high exhaust line, would show less work than could be obtained with the lower exhaust line that would be found in practice. A better theoretical representation of practical conditions would be the locomotive-cycle diagram *ABNPDA*.

The work developed in the locomotive cycle is easily calculated by the use of the steam tables. Take for example the diagram *ABEFDA*, representing admission at 350 lb. per sq. in., release at 50 lb. per sq. in., and exhaust at 25 lb. per sq. in. The area of this is *ABELA* with *LEFD* added. The former represents the work done in the Rankine cycle from 350 lb. per sq. in. to 50 lb. per sq. in. As the heat content is 1338 B.t.u. at 350 lb. per sq. in., and 1154 B.t.u. at 50 lb. per sq. in., the area *ABELA* represents $1338 - 1154 = 184$ B.t.u. The area *LEFD* represents the product of the volume *LE*, in this case 8.30 cu. ft., multiplied by *EF*, the difference between the release pressure *EM*, 50 lb. per sq. in., and the exhaust pressure *FM*, 25 lb. per sq. in. Therefore the area *LEFD* represents $0.152 \times 8.30(50 - 25) = 37$ B.t.u. Consequently the total work of the diagram *ABEFDA* is

$$184 + 37 = 221 \text{ B.t.u.}$$

By carrying out similar calculations for various release pressures with admission pressures of 800, 600, 450, 350, and 220 lb. per sq. in., the values given in column 7 of Table 1 are obtained.

TABLE 1 EXPANSION CONDITIONS OF STEAM OF 650 DEG. FAHR. EXPANDED FROM 800, 600, 450, 350, AND 220 LB. PER SQ. IN. TO VARIOUS RELEASE PRESSURES AND THEN EXHAUSTED AT 25 LB. PER SQ. IN.

| | 25 | 1143 | 0.981 | 16.0 | 5.48 | 203 | 15.1 |

This table consists of five panels, one for each of the admission pressures considered. Column 2 shows the various release pressures to which expansion from the admission pressure is supposed to be carried. Columns 3, 4, and 5 show respectively the total heat, the quality, and the volume of the steam after expansion to the release pressure. Column 6 gives the number of expansions, that is, the volume at release divided by the volume at the end of admission. Column 7 gives the amount of heat transformed into work in the locomotive cycle, that is, expansion to the release pressure and exhaust at 25 lb. per sq. in., while column 8 gives the thermal efficiency of the cycle, that is, the heat transformed into work expressed as a percentage of the total heat energy in the steam on admission.

The figures in Table 1 show the effect of admission pressure and ratio of expansion on the thermal efficiency of the steam in the cylinders. For the first line in each panel the release pressure is the same as the admission pressure, so that there is no expansion, a rectangular full-stroke diagram, as *ABTDA* in Fig. 1, being obtained. Under these conditions the work done is the external work of the steam entering the cylinder less the work lost by exhausting against the back pressure of 25 lb. per sq. in. It will be seen that with this full-stroke cut-off the admission pressure has very little effect on the work done per pound of steam or on the thermal efficiency. The range is only from 105 to 109 B.t.u. per lb. of steam and from 7.9 to 8.1 per cent thermal effi-

ciency. Increase of the ratio of expansion gives an increase in efficiency which is more rapid with the higher admission pressures.

This is clearly shown in Fig. 2, in which the computed thermal efficiency of the cylinders is plotted against the ratio of expansion for each of the five admission pressures. Up to two expansions there is little perceptible difference in efficiency for pressures between 220 and 800 lb. per sq. in. Above this point the efficiency rises faster with the higher pressures than with 220 lb. per sq. in., but nearly 3 expansions are reached before the difference between 350 and 800 lb. per sq. in. is noticeable.

The curves for each pressure are carried up to the degree of expansion at which the pressure is reduced to 25 lb. per sq. in.

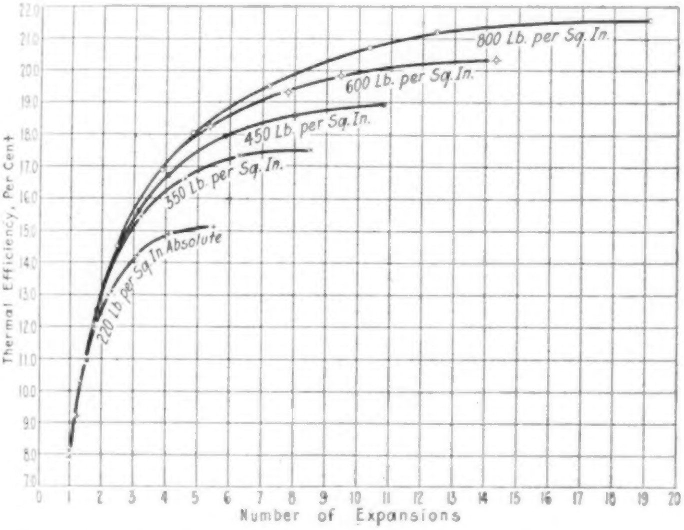

FIG. 2 RELATION BETWEEN CYLINDER EFFICIENCY AND EXPANSION FOR VARIOUS STEAM PRESSURES

(In all cases: Admission temperature, 650 deg. fahr.; exhaust pressure, 25 lb. per sq. in.)

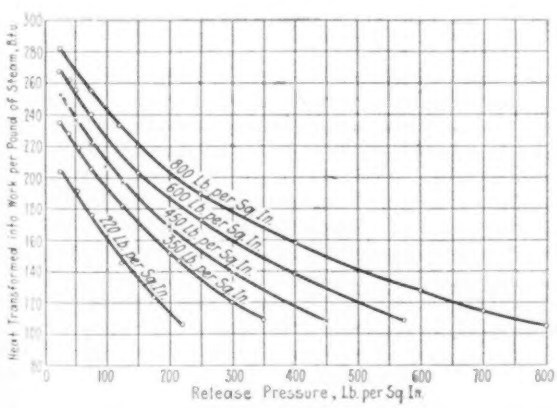

FIG. 3 THEORETICAL DIAGRAMS FOR VARIOUS STEAM PRESSURES, ADIABATIC EXPANSION

(Admission temperature, 650 deg. fahr.; release pressure, 50 lb. per sq. in.; exhaust pressure, 25 lb. per sq. in.)

This is of course a greater expansion than is usually attainable in practice. If the steam conditions only are considered, and the details of cylinders and valve motions required for high expansion are neglected for the present, it may be taken as possible to expand the steam down to 50 lb. per sq. in. and then to release and expand at 25 lb. per sq. in. Under these conditions the figures shown in Table 2 are obtained. To release at 50 lb. per sq. in., 3.12 expansions are required from 220 lb. per sq. in., 4.6 expansions from 350 lb. per sq. in., and so up to 10.35 expansions for 800 lb. per sq. in.

The thermal efficiency in each case is shown in column 6. The values rise from 14.2 per cent with 220 lb. per sq. in. to 17.9 per cent with 450 lb. per sq. in., and 20.7 per cent with 800 lb. per sq. in. These three values bear to each other, as shown in column 7, the relation of 100, 126, 146. That is to say, a rise of pressure of 230 lb. from 220 to 450 lb. per sq. in. raises the efficiency by 26 per cent of its value, while a further rise of 350 lb. from 450 to 800 lb. per sq. in. only adds another 20 per cent. That is to say, the higher the steam pressure the less it is possible to gain by a still further increase. The law of diminishing returns comes into operation. This statement is based only on theoretical thermodynamic considerations and does not take into account that as the pressure is increased the expansion must be

lengthened, which will eventually introduce mechanical difficulties with cylinders and valve motion. In addition, each increase in boiler pressure tends to increase the boiler weight and to complicate the design. Taking all these matters into consideration, it appears probable that for the present it will be found that the most economical pressure for construction, maintenance, and operation will be found not to exceed 500 lb. per sq. in.

In order to help to visualize the effect of high admission pressures, diagrams corresponding to the conditions of Table 2 are plotted in Fig. 3 for 220, 350, 450, and 800 lb. per sq. in. In Fig. 4 data from Table 1 are plotted to show for the various admission pressures how the work developed per pound of steam in the locomotive cycle varies with the release pressure.

So far we have dealt with the theoretical expansion of the steam under ideal conditions. In Figs. 6 and 7 the diagram of the ideal locomotive cycle is compared with indicator diagrams taken from an actual locomotive. Fig. 5 reproduces indicator diagrams taken from a three-cylinder compound locomotive operating with a boiler pressure of 350 lb. per sq. in. gage. The three cylinders all have the same dimensions, 27 in. diameter by 32 in. stroke, and are compounded with one cylinder as high-pressure and the other two as low-pressure.

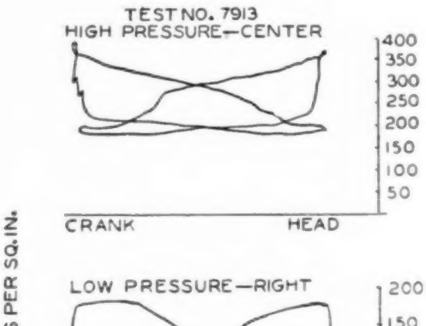

Fig. 5 Actual Indicator Diagrams for Locomotive 60,000 Having One High-Pressure Cylinder and Two Low-Pressure Cylinders

(Steam in branch pipes, 333 lb. per sq. in., 634 deg. fahr.; steam per i.hp-hr., 14.2 lb.)

The low-pressure volume is therefore twice that of the high. The broken-line diagram in Fig. 6 represents the high- and low-pressure cards with the effect of the clearance steam eliminated, and with the low-pressure card drawn to a double scale horizontally. Around this is drawn in full lines the theoretical indicator diagram for the locomotive cycle with expansion to 50 lb. per sq. in. The shaded area between the actual and theoretical cards represents losses by heat transfer between steam and cylinder and by friction in the ports. It will be noted that during admission there is a drop of pressure, but that before release takes place the expansion line comes out to coincide very nearly with the theoretical line representing adiabatic expansion.

This shows that of the heat given up by the steam to the cylinder during admission a large part is returned to the steam

(Work per pound of steam: Theoretical, 222 B.t.u.; actual, 174 B.t.u. = 78.5 per cent.)

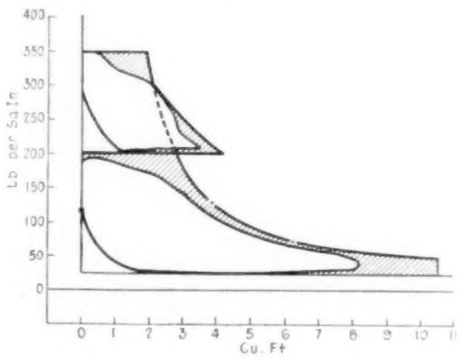

Fig. 7 Adiabatic Expansion of Steam From 350 Lb. per Sq. In. and 650 Deg. Fahr., Compared With Actual Cards From Locomotive 60,000—Effect of Clearance Steam Included

during expansion, so that the actual pressure-volume curve does not drop so rapidly as does the adiabatic curve. The measured steam consumption during the test was 14.2 lb. per i.hp-hr., which corresponds to 174 B.t.u. transformed into work per pound of steam. The theoretical diagram shows 222 B.t.u. transformed per pound, so that the actual area is 78.5 per cent of the theoretical area. The actual ratio of expansion is from 1.8 cu. ft. to 6.4 cu. ft., or 3.6 expansions as against 4.6 expansions in the theoretical locomotive cycle.

Fig. 7 is similar to Fig. 6, except that here the effect of the clearance steam is shown. This shows that in order to provide for 3.6 expansions of the working steam the cylinder volume at the end of the stroke has to be 8.3 cu. ft. That is, the clearance steam makes it necessary to have 30 per cent more cylinder volume than is called for by the theoretical diagrams previously discussed. Consequently, to obtain high efficiency with the higher pressures it will be necessary to use even shorter cut-offs than are indicated by Tables 1 and 2.

## Conclusions

The pressure of 220 lb. per sq. in. absolute used in the calculations corresponds to a boiler pressure of 205 lb. per sq. in. gage. It is evidently possible to secure a considerable increase in the thermal efficiency of the cylinders by increasing the boiler pressure. To secure the full possible increase in efficiency the ratio

of expansion must be increased. This can be done by the use of a special valve motion or compound cylinders, or both. The use of three cylinders makes compounding a very simple matter, and results obtained in practice are very satisfactory. Probably when everything is considered, construction, maintenance, and operation, it will be found inexpedient for the present to use boiler pressures much over 450 lb. per sq. in. gage.

## Discussion

R. Eksergian.[4] The locomotive cycle used by the author approximates an actual cycle; however, actual performances require the use of a cycle factor, which must take care of the equivalent ratio of expansion with a given clearance volume, the cooling, or condensation, effect of the steam during admission in the clearance space, wire drawing and throttling, and the corresponding decrease of availability, the reheating factor which modifies the expansion curve from an adiabatic, the proper compression and its effect on the card, etc.

Therefore, in the same degree of precision to analyze the advantage of raising the pressure and increasing the expansion ratio, careful consideration should also be given to the modification of the cycle factor, which in general can be shown to appreciably decrease with increased pressure and high expansion ratios. The factor, of course, would be different, depending upon whether the steam expanded in a single cylinder or was compounded in two cylinders.

The author has pointed out certain advantages in compounding; that is, the expansion in two cylinders rather than one. It is interesting to compare such expansions.

With simple cylinders, with increasing expansion ratios the cut-off necessarily must be reduced until a condition is reached where the percentage of clearance volume to cut-off volume becomes so large that the loss due to cooling during admission offsets the gain due to expansion. Thus we become definitely limited to given expansion ratios with simple cylinders. The expansion ratio being at best relatively small for any ideal cycle, the clearance volume itself has, therefore, a marked effect on the ratio of expansion. A further disadvantage of single-cylinder expansion is the abnormal ratio of peak to mean piston load, if advantage is to be taken of better expansion ratios, which necessarily must go with increase of pressure at low speeds. This, therefore, requires heavier machinery at the expense of a smaller boiler, with poorer counterbalance conditions.

Compounding offers advantages in the use of greater expansion ratios which are needed to take care of the higher pressures. An outstanding advantage is the greater range of economical performance, because (1) a reasonably good expansion ratio can be obtained at low speeds, and (2) the possibility of relatively greater expansion ratios due to the fact that the cooling effect of the clearance space is reduced. The throttling loss is increased over that of a simple cylinder, but the greater gain in better expansion ratio overbalances this.

H. B. Oatley.[5] The question of pressure must go along with the question of steam temperature, and in the most advanced design of high-pressure power plants the use of reheating or intermediate superheating is also carefully considered. It would have been very interesting if Mr. Fry had extended the first and second sections of Table 1 to show the gain by reheating at 200 lb. or 250 lb. pressure.

The practical problem of reheating is, of course, far harder for the locomotive designer with the limited space available than it is for the industrial-plant designer. The Schmidt-Henschel double-pressure locomotive on the German State Railways impresses one with the fact that an attempt has been made to provide what, in reality, is interstage reheating and at the same time to reach some of the economies which are to be found in the use of steam pressures now being utilized in central power stations and modern industrial plants. The locomotive is of more than ordinary interest because of the marked advance toward higher steam pressures, carrying as it does a working pressure of between 850 and 900 lb. per sq. in., and also because of the double-pressure arrangement of the boiler. This method of steam generation has been provided, and reciprocating engines retained, in an effort to obtain a much more economical unit than any steam locomotive thus far used and to do this by means of a construction far less expensive, equally safe and practicable, and more easily maintained than can be had by the use of an internal-combustion or turbine prime power. Comparisons which will be shown include the performance of other locomotives working with what may be termed high steam pressures, which are to be understood as 250 lb. per sq. in. and upward.

The records of this locomotive support the thermal analysis

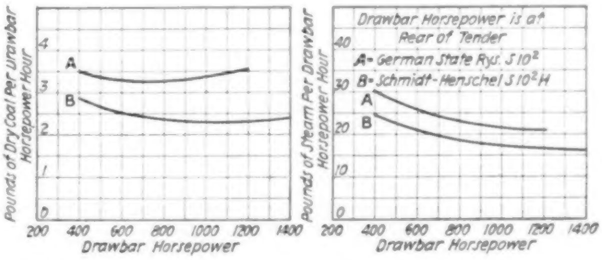

Fig. 8 Water and Fuel Rate Plotted Against Tender Drawbar Horsepower of the German State Railways 4-6-0 Type Before and After Conversion to the Double-Pressure Design

of Mr. Fry. The steam pressures used, however, are above the limits set forth in his paper, but evidently Mr. Fry's limits, as regards pressure, are premised on the use of a single-pressure generator and on the shell of the fire-tube boiler carrying the maximum pressure given to the high-pressure cylinders.

The following data on the Schmidt-Henschel locomotive have been made available through the courtesy of R. P. Wagner, chief of the motive-power division of the Deutsche-Reichsbahn, and S. Hoffman, managing director of the Schmidt'sche Heissdampf Gesellschaft. The tests were run on the Berlin-Magdeburg division of the German State Railways, and dynamometer-car records were used.

Table 3 compares this locomotive with the Pennsylvania I1s class 2-10-0 type locomotive, with the Baldwin experimental 4-10-2 type locomotive No. 60,000, and with the German State S-10-2 class, 4-6-0 type, with normal boiler, of which a large number are in service. The Schmidt-Henschel S-10-2E locomotive was constructed by rebuilding one of the S-10-2 locomotives.

Attention is invited to the fact that in point of size the double-pressure locomotive is, in comparison with the two American-built locomotives, a very small unit, and it may reasonably be expected that had this experimental engine been of a size comparable with the modern American locomotive, there would have been obtained a still lower fuel and water rate per unit of power developed.

Fig. 8 shows the water and fuel rate of the German locomotive plotted against drawbar horsepower before and after its conversion to the double-pressure method of steam generation.

[4] Engineer, Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

[5] Vice-President in Charge of Engineering, Superheater Company, New York, N. Y. Mem. A.S.M.E.

The reduction in water and coal consumption through the change in boiler and cylinders is clearly evidenced. In comparing these unit figures it must be kept in mind that the horsepower values are at the rear of the tender.

In Fig. 9 the water rate plotted against drawbar horsepower at the rear of the engine under test-plant conditions is shown. Curve *A* shows the performance of the Pennsylvania I1s class 2-10-0 type locomotive, curve *B* of the Baldwin 4-10-2 type locomotive No. 60,000, and curve *C* of the double-pressure locomotive.

and steam of lower pressure, also superheated, delivered with the steam exhausted by the high-pressure cylinder to the low-pressure cylinders. The low-pressure cylinders, therefore, are working with a much higher temperature than would be possible unless steam of an impracticably high temperature was delivered to the high-pressure cylinder.

Fig. 10 is on the same basis as Fig. 9 and shows coal per drawbar horsepower-hour against drawbar horsepower. The same striking reduction in the fuel consumption per unit of power is noticeable. This is the result of the factors which have produced a reduction in steam consumption and also of the improved boiler performance which the design provides.

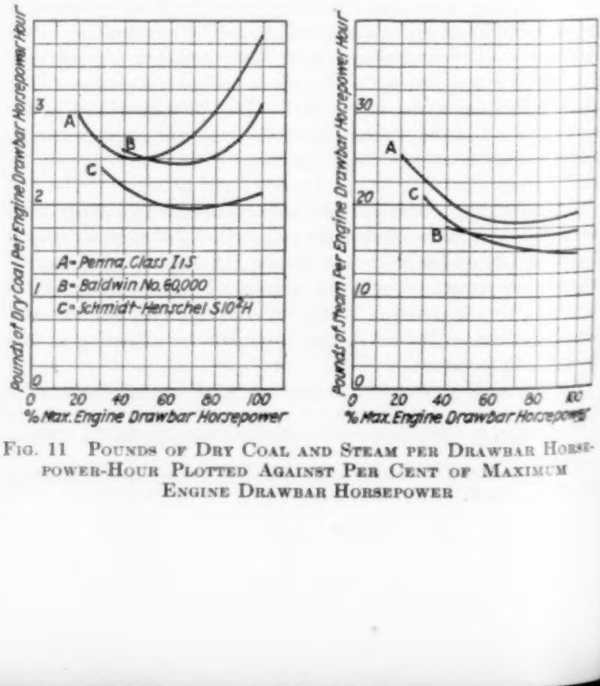

FIG. 11 POUNDS OF DRY COAL AND STEAM PER DRAWBAR HORSEPOWER-HOUR PLOTTED AGAINST PER CENT OF MAXIMUM ENGINE DRAWBAR HORSEPOWER

From the illustrations shown, the fact that the maximum horsepower of these locomotives is not directly comparable because of their difference in size, the relative performance at any given percentage of maximum power is not so clearly evident. To make this a little clearer, Fig. 11 has been prepared showing the steam and dry coal per drawbar horsepower-hour, measured at the engine drawbar, plotted against percentages of maximum locomotive capacity in terms of engine drawbar horsepower. These curves naturally bring the same percentage of power in the same vertical line, and are another way of illustrating the possibilities of further improvement in locomotive economy from a steam and fuel standpoint.

As was to have been expected, a number of difficulties were encountered in this first double-pressure locomotive, but all were of a relatively minor character and have been successfully overcome. Boiler-feeding devices originally applied were not entirely suitable. The means for indicating the water level required some modification. The performance of the locomotive showed that this system of steam generation and use was a perfectly satisfactory, safe, and efficient design. It has been particularly noticeable that there have been no changes necessary in the method of handling the locomotive, and that the engine crews have had no difficulty in adapting themselves to its operation. This is a factor of very great importance when considering new types of steam locomotives where internal-combustion engines or turbines with various power-transmission devices are utilized, and where a very complicated and delicate condensing apparatus has to be used.

The results of these tests fell short of the expected best performance, and some changes are now being made which are confidently expected to provide an additional 10 per cent in fuel economy.

The writer was given the opportunity of making a thorough inspection of this locomotive after the tests had been completed. This inspection confirmed the claims that have been made for the practicability of the Schmidt method of steam generation for locomotive service. The indirect method of steam generation utilized in this locomotive has been used for some time in power plants for stationary service. The writer visited two such power plants where the working steam pressure at the prime movers, which incidentally were reciprocating steam engines, was in excess of 50 atmospheres (735 lb. per sq. in.). Additional confirmation of the satisfactory operation of this type of steam generator was found.

The indirect method of steam generation offers advantages which may in part be described as follows:

1 The high-pressure drum is not in direct contact with the high-temperature gases.

2 The steam generation in the high-pressure drum is uniformly distributed throughout the entire length of the drum. The separation of steam from water, therefore, is more evenly distributed and the so-called geyser action, found in normal boilers, is eliminated. The result is a smaller moisture content in the steam being taken from the pressure boiler.

3 The circulation of water through the indirect heating system is influenced only by the temperature conditions in the firebox. There is no opportunity for an unfavorable circulation caused by other conditions.

4 No stayed surfaces are used either in the indirect heating system or in the high-pressure steam drum. The safety, therefore, of all parts carrying the high pressures is increased.

5 Firing up of a boiler with the indirect heating system can be done much more rapidly and with less stressing of the boiler material than with the usual type of steam generator.

6 The heating surfaces in the high-pressure drum are practically scale free, since its feedwater is taken from the low-pressure boiler where whatever scale-forming material that is introduced remains.

The cleaning of the high-pressure boiler consists simply of washing out any soft sludge which may accumulate. The indirect heating system is a closed circuit and uses water which is scale and corrosion free.

Geo. A. Orrok.[6] The chief difficulty with the high-pressure locomotive lies not in the engine but in the boiler. The magnitude of the pressures depends entirely upon the track gage. The width of the track settles immediately the size of the low-pressure cylinders, and therefore the pressures that can be carried economically.

The boiler problems, on the other hand, become matters of type and construction. The type and manner of construction must be such as to insure satisfactory operation over the usual humps and hollows of the average railway.

This new development of the Schmidt-Henschel locomotive is very interesting because of the absence of many of the difficulties of the high-pressure boiler. This type of boiler is at present occupying the attentions of European designers to a considerable extent. In addition to the work of Messrs. Schmidt and Hartmann, exemplified in the Schmidt-Henschel locomotive, there is the Löffler type of boiler which employs virtually the same idea, that is, of obtaining the high pressures by means of superheated steam so that the vessel containing the high-pressure steam is not subjected to the heat of the furnace. A third type patented by Brown, Boveri and Company eliminates the circulating pump employed in the Löffler type.

The record of 2 lb. of coal consumed per drawbar horsepower-hour is a very excellent performance for a locomotive. This corresponds to approximately $2^3/_4$ lb. per kw-hr. and compares very favorably with the average central-station performance of a few years ago when a consumption of 3.2 lb. of coal per kw-hr. was common. At present the average central station in the United States requires 1.9 lb. of coal per kw-hr., and the best stations run around 0.8 lb.

Considering the fact that locomotives formerly demanded 8 to 9 lb., the record of 2 lb. would seem to approach very nearly the limit on the sizes in use today. It may be possible to drop below that figure, but to obtain the required draft it is necessary to permit some losses.

Lately, the writer has been devoting considerable thought to the length of time our present steam locomotives are going to meet the competition of the new designs. Five different types of turbine locomotives and as many as seven or eight Diesel-engine-powered units have been examined. The former does not seem to be of commercial value at present. The Diesel-engined locomotives appear to be working satisfactorily. Present locomotives of this type, however, are rather small and have been used chiefly for switching service and branch-line work. As far as the writer can see, the future does not hold great promise for this type on our present gage of track. In Russia, where a wider gage is used, it may be possible to build a Diesel locomotive of reasonable size. With the United States standard gage it would be necessary to couple three, four, or possibly five units together to obtain the work required.

It appears that while we may not retain our present design of locomotive, future equipment will of necessity be somewhat similar. Of all experimental engines examined none promises such good results as our own old-fashioned American locomotive type. Three cylinders may be adopted, compounding may follow, and undoubtedly higher pressures than are common today will eventually be employed, but a great deal of work will be

[6] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

done with the ordinary American type for a great many years.

The Author. It is interesting to find that those discussing the paper are so nearly in agreement with the author. Mr. Oatley's information regarding the Schmidt-Henschel locomotive with double-pressure boiler is a valuable record of the performance of a locomotive that deserves very careful study from any designer who is out for the highest possible cylinder efficiency. Since the paper was written the author has had the privilege of riding on this locomotive and as a result is able to confirm Mr. Oatley's statements. Mechanically the German locomotive seems to do all that its designers expected, and where fuel is expensive it will make a strong claim for consideration. There may be some question, however, as to whether for general service the greater first cost and maintenance will not offset the possible saving in fuel.

# Back Pressure and Cut-Off Adjustment For the Locomotive

By THOS. C. McBRIDE,[1] PHILADELPHIA, PA.

*This subject is discussed from the operating standpoint only. The author presents data showing the indicated horsepower, the steam consumed, and the dry coal fired as functions of the back pressure. He points out that for each locomotive there is a certain back pressure at which maximum power can be obtained at the lowest cost. He advocates a method to determine the best back pressure experimentally, and the use of back-pressure gages for the guidance of the locomotive engineers.*

BACK pressure, as generally understood in connection with the locomotive, may be defined as the pressure of the exhaust steam in the exhaust ports in the cylinder saddle of the locomotive. It has been studied for years in connection with the design of details of the locomotive to the end that it might be reduced to a minimum in the interest of economical operation and increased capacity.

About three years ago, a use for back pressure in the operation of the locomotive was developed. This development followed a demonstration of the fact that the back pressure could be used to indicate the length of cut-off that should be used to obtain maximum power from the locomotive and also to avoid the waste of steam and fuel that would result from the use of an unnecessarily long cut-off. These two viewpoints, that of the designer and that of the operator, should not be confused. It is from the latter standpoint only, presuming that the locomotive has been properly designed, that back pressure and cut-off are considered in this paper.

The first complete demonstration of the principles involved with which the author is familiar is contained in a paper presented by R. W. Retterer before the International Railway Fuel Association at their meeting in May, 1925, and published in the Proceedings of that association. In that paper it was demonstrated that the power that could be obtained from the cylinders of any particular locomotive was limited to a certain definite maximum at any speed high enough to obtain that power, and that when the cut-off was so adjusted that this maximum cylinder power was obtained, the same back pressure was obtained at all speeds. The cylinder power is limited because the further extension of a cut-off already long enough, although it raises the top line of the indicator card and increases the area to that extent, also raises the bottom line of the indicator card and decreases the area to the same or perhaps a slightly greater extent; all because of the increased back pressure due to the greater amount of steam that must pass through the blast nozzle.

Mr. Retterer's paper also described an experiment with a locomotive equipped with a gage in the cab to indicate the the back pressure. The piping connecting this gage to the exhaust ports of the locomotive was provided with a uniflow fitting. This locomotive and a certain train were run six times up a certain grade for a distance of 10,000 ft. The cut-off was kept so adjusted on each run that back pressures of 10, 12, 13, 14, 16, and 20 lb. per sq. in., respectively, were maintained on the back-pressure gage. A maximum speed of 27 miles per hour was obtained on the run with 13 lb. back pressure, and maximum speeds of practically 24 miles per hour were obtained on the runs with 10 and with 20 lb. back pressure. The greatest power must have been obtained with 13 lb. back presssure and less, but about the same power with both 10 and 20 lb. back pressure. The total steam used on the 10,000-ft. run was about the same for 10, 12, and 13 lb. back pressure, but for back pressures above 13 lb. the total steam used increased practically in proportion to the increase in back pressure. From this experiment it must be concluded that any cut-off which resulted in a back pressure of less than 13 lb. did not realize the full possible power of the locomotive, while any cut-off which resulted in a back pressure greater than 13 lb. meant less power developed and more steam consumed—with the chance that the boiler pressure might drop and the train stall.

In order to determine more definitely the relation between back pressure, indicated horsepower, steam consumption, and fuel burned, use has been made of the bulletins published by the Pennsylvania Railroad System from their Locomotive Test Plant at Altoona, Pa. In Fig. 1 these items have been plotted as taken from the bulletin, dated 1915, which reports the test of a P.R.R. standard Mikado, type L-1s locomotive which had the usual standard injector equipment.

Referring first to the solid-line curves marked "injector," it is noted that:

1 The i.hp. reaches a definite maximum of 2750, beyond which no further increase in power is to be expected, and when this maximum is reached the back pressure is 16 lb.

2 The fact that the various points indicating i.hp. fall so close to a smooth curve indicates that maximum power is obtained when the cut-off is so set that a back pressure of 16 lb. is obtained, at least for all the speeds at which tests were made at this power. It might be expected that more power would be developed with the same back pressure at higher speed and shorter cut-off; in fact, the points plotted show a slight tendency in that direction, and in some other plots that had been made this tendency is more pronounced. The points for 100 r.p.m., it is true, are well below the curve, but the points for 80 r.p.m. which have not been plotted fall almost exactly on the curve. Even if it is concluded that, with the same back pressure, more power is developed at higher speed and shorter cut-off, it still remains true that the points plotted indicate that the maximum power for *each* speed is obtained at one and the same back pressure, and the usefulness of back-pressure indication of proper cut-off to obtain maximum power is not lessened.

3 The curves "steam to engine" and "dry coal fired per hour" also show points falling quite close to a smooth curve, and steam and fuel consumption increasing at a rapid rate as the back pressure which represents maximum power is reached.

It is doubted whether locomotives are operated on the road for any very long periods at the excessive rates to which they are forced on the test plant, principally because of the difficulty in maintaining steam pressure. It is noted also that the last 100 i.hp. developed require 7000 lb. of steam and 2400 lb. of coal per hour, and are obtained at an almost prohibitive cost. These two features seem to indicate that, instead of attempting to obtain the outside maximum cylinder power possible through

[1] Consulting Engineer, Locomotive Feedwater Heater Dept., Worthington Pump & Mchy. Corp., Philadelphia, Pa. Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

the use of a cut-off resulting in 16 lb. back pressure, it might be advisable to use a slightly shorter cut-off, resulting in, say, 13 lb. back pressure, with the assurance that the boiler pressure would be maintained and with the avoidance of the expenditure of so much more fuel to obtain just a little more power. Here, then, the engineer should be instructed to keep the cut-off so adjusted that a back pressure of 13 lb. is obtained whenever maximum power is desired. A shorter cut-off, indicated by a back pressure

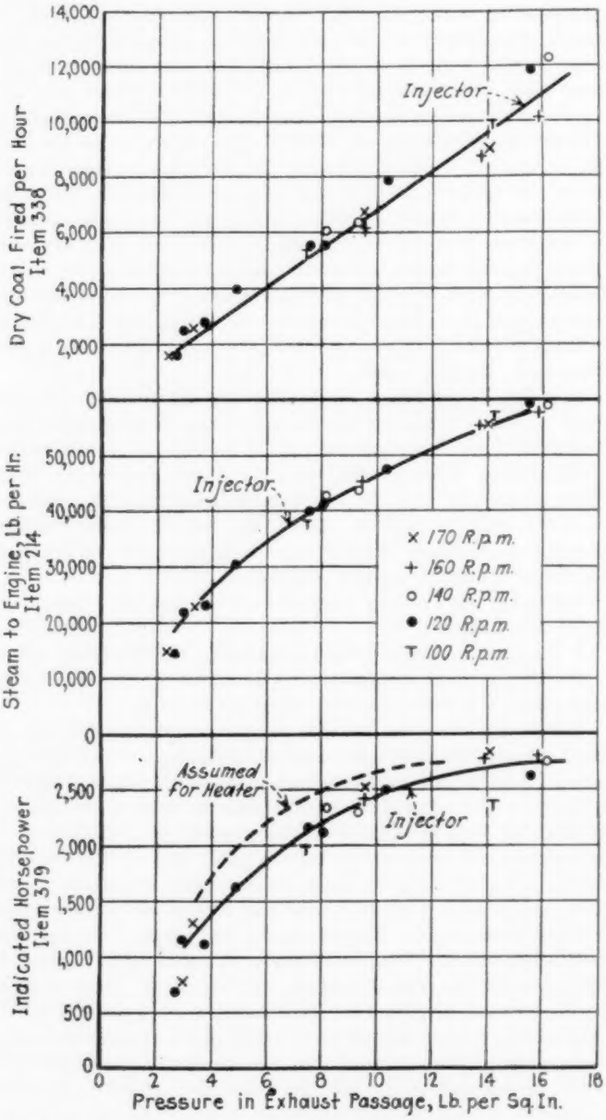

Fig. 1 Data From Pennsylvania Railroad Locomotive Test Plant

(Bulletin No. 28, Pennsylvania Railroad Co. L-1s Mikado Locomotive.)

of less than 13 lb., would not realize the full possible power of the locomotive. A longer cut-off, indicated by a back pressure of more than 13 lb., would not realize any more, but probably somewhat less, power developed. More steam would pass through cylinders, more fuel would be burned and this additional fuel wasted, and with a cut-off much too long the capacity of the boiler might be exceeded and the steam pressure drop.

Question naturally arises as to when or under what operating conditions of the locomotive back pressure can be made useful in its indication of the proper adjustment of the cut-off. There are roughly four different conditions of operation on the road to be considered as concerning the adjustment of the cut-off:

1 *Drifting*, when the length of cut-off is determined by mechanical and not economic conditions.

2 *Light power*, when the cut-off should be as short as smooth operation of the locomotive will permit and the speed controlled by the throttle and the length of cut-off again dictated by mechanical conditions.

3 *Medium power*, when the throttle should be full open and the speed controlled by the adjustment of the cut-off. The length of cut-off is dictated by the speed required, the steam is used economically, and nothing further is needed to assure the use of a cut-off of proper length.

4 *Maximum power and powers approaching the maximum*, when the throttle should be full open and the cut-off only as long as is necessary to secure the maximum cylinder power. It is under this condition alone that the back-pressure gage can be of use as an indication of the best adjustment of the cut-off. Modern conditions have required the operation of locomotives at maximum or near maximum powers a large portion of their time on the road. The back-pressure gage should be of great assistance in meeting this requirement.

Incidental advantages of the back-pressure gage at powers other than maximum have already been noted, but these are generally foreign to the determination of the proper adjustment of the cut-off and the economic operation of the locomotive.

Now that there are over 5000 locomotives equipped with feedwater heaters in service in the United States and Canada, the indications of the back-pressure gage with the feedwater heater in service demand consideration. The same or practically the same length of cut-off is required for the same power developed by the heater locomotive and by the injector locomotive, but the back pressure on the heater locomotive is lower because of the exhaust steam taken by the heater to heat the feedwater. No tests have been made on the test plant and, as far as the author is advised, no tests have been made on the road showing comparable data on heater and injector operation of the same locomotive at powers approaching the maximum for the cylinders. It has therefore been necessary to calculate the relation between back pressure and i.hp. for the heater locomotive. This relation is shown by the dotted curve of Fig. 1. In laying out this dotted curve it was assumed that for the same power developed the back pressure obtained would be that corresponding to 15 per cent less steam than is shown by the "steam to engines" curve, inasmuch as approximately 15 per cent less steam would pass through the blast nozzle of a heater locomotive with water at the temperature of the water used in this particular test-plant test.

It is noted from the curves that the maximum cylinder power of 2750 i.hp. is obtained with the heater locomotive with a cut-off which results in 12 lb. back pressure as compared with 16 lb. back pressure for the injector locomotive, and that this cylinder power could be maintained with the heater locomotive because it requires 8200 lb. of coal burned per hour, whereas the same power could not likely be maintained by the injector locomotive because it requires the burning of approximately 11,000 lb. of coal per hour. Greater sustained maximum power is possible because of the feedwater heater. The back-pressure gage, properly used, offers the same assurance that this greater sustained maximum power will be obtained from the heater locomotive that it presents for the obtaining of maximum power from the injector locomotive.

It is a well-known fact that there is a tendency to operate locomotives by "the sound of the exhaust," this sound at least influencing the engineer's judgment in the adjustment of the

cut-off. If a heater is applied to a locomotive and the locomotive operated with the cut-off so adjusted that the exhaust sounds the same as it sounded previously with the injector, then the back pressure must be the same and, consequently, the same amount of fuel is burned with the heater as with the injector. One result would be obtained with such operation at medium powers of the locomotive and a quite different result at maximum or near-maximum powers. Referring to Fig. 1, it will be noted that at medium powers more power will be developed with the heater, which, with the same tonnage, will appear as increased speed. The same amount of fuel is burned but more power is obtained, and the heater is used to increase the capacity of the locomotive rather than to save fuel. At maximum or near-maximum powers, however, with the same sound of the exhaust and the same fuel burned, the same power would be developed. For example, referring again to Fig. 1, with 14 lb. back pressure, 2700 i.hp. would be developed and 9600 lb. of coal burned, both with the heater and with the injector. The saving in fuel obtained from the heater is cancelled by the unnecessarily large amount of steam supplied to the cylinders due to the use of entirely too long a cut-off with the heater. The back-pressure gage can be used to determine and demonstrate this lower back-pressure necessary with the heater if full advantage is to be taken of the heater.

Since a considerable number of exhaust-steam injectors are in service, an attempt was made to develop the relation between back pressure and power developed with them, but too many assumptions are necessary. These injectors are generally so selected as to size that the ordinary working rates of the locomotive are above their minimum capacity and the maximum capacity of the locomotive is then generally above their maximum capacity. Furthermore, the amount of exhaust steam that can be used by the exhaust-steam injector varies with the capacity at which it is worked, and the amount that is used varies with the adjustments made. The reduction in back pressure with the exhaust-steam injector in service is therefore a variable quantity that would make it difficult to interpret the readings of the back-pressure gage as an indication of cut-off adjustment.

It is evident from all of the above that if back pressure is to be used to secure proper operation of the locomotive as to cut-off, then some method must be developed to determine experimentally the best back pressure, i.e., the back pressure which results from the shortest length of cut-off that will develop the maximum power that can be maintained with each railroad class of locomotive when the speed is high enough to obtain that power. The method most used to date has been that of operation by an expert whose judgment is depended upon to determine the best back pressure. The method used by Mr. Retterer as described in his paper submitted to the International Railway Fuel Association, and briefly in this paper, obtains more exact information. Where a locomotive has been tested on the test plant the best back pressure can be determined by the method suggested in Fig. 1. Where a dynamometer car is available or in use for other purposes, simultaneous readings of the back pressure and drawbar horsepower developed could be plotted and the minimum back pressure, and therefore minimum steam consumption for maximum drawbar horsepower, thus obtained.

By these methods the best operating cut-off is determined for each class of locomotive. The back-pressure gage supplies a permanent record of this best operating cut-off and makes it possible to reproduce it in every-day operation on the road with the assurance that maximum power when required will be immediately obtained, and that without the supply of unnecessary steam and consequent waste of fuel.

The "position of the reverse lever" has been appreciated as a very important factor in the operation, and particularly the economic operation of locomotives. The individual performance of the engine men varies widely both in the handling of the locomotive and in fuel consumption. *Railway Age* of June 19, 1926, reported some tests of individual performance on the Union Pacific Railroad and stated:

> On analyzing the results, it was found that the individual performance of one of these enginemen when compared with the other nine as a group showed a saving in fuel per thousand gross ton-miles of 17 per cent. The tests also showed that in this group of nine enginemen there were individuals falling as much as 30 per cent below the best man. * * * * * * * one or two enginemen were found whose performance was such that it could scarcely be improved, while one individual engineman was found using as high as 45 per cent more fuel per 1000 gross ton-miles than was demonstrated by the test to be necessary.

Such wide variations in individual performance are not at all unusual. Of course, condition of equipment, weather, etc. must be considered, but Mr. Retterer's experiment and Fig. 1 indicate that the individual habit in the adjustment of the cut-off can and must be largely responsible for these very wide variations. The essentials necessary for good cut-off adjustment can scarcely have been appreciated in the past since many locomotives are supplied with reverse-lever quadrants with notches so coarse that it is impossible to make the fine adjustments of the cut-off which have been demonstrated to be necessary. It is evident that something better and more exact than the judgment of the enginemen is needed to indicate the best adjustment of the cut-off in order that this adjustment may be made exactly and quickly. The back-pressure gage properly used should fill this need.

## Discussion

E. S. Pearce.[2] The theoretical soundness of back-pressure regulation as a means of accurate cut-off adjustment has been very definitely established by Mr. McBride.

An investigation of the operation and development of this principle, as carried on for some eight years, might clearly indicate that a full realization of the benefits reasonably to be anticipated cannot be obtained through the medium of back-pressure gages located in the cab to which back-pressure steam is conveyed from the exhaust passages of the cylinders. Conclusively, neither the gage, the cut-off adjusting means, nor the engineman are accurate, dependable or constant.

The regulation of cut-off to any constant back pressure must be done within a total range of $1^1/_2$ lb. of the constant. The indicating means must be free of pulsations, yet it must not lag behind changes in the cylinder exhaust.

Gages subject to pulsations deteriorate rapidly and become inaccurate. Choking the pressure line to protect gages retards transmission of changes with proper rapidity, and therefore adjustments are not in keeping with cylinder exhaust conditions. The gage, under any condition, is inaccurate because of the hydraulic head of condensed steam in the back-pressure pipe. The gage in the cab may be four to eight feet higher than the cylinder. Condensed steam, which exists in a greater or lesser degree, produces a hydraulic head of varying amount, which the cylinder exhaust pressure must sustain, and the gage indicates the differential, not the cylinder exhaust pressure.

The reversing mechanism, for either manual or power operation, generally in use on locomotives has not been designed or applied with the idea of obtaining accuracy of adjustment or positive holding power necessary to produce or maintain cut-off settings of the required fineness.

[2] President, Railway Service & Supply Co., Indianapolis, Ind. Mem. A.S.M.E.

Finally, the engineman, who must provide the additional mental and physical effort over his now customary operation, is quickly aware of the inadequacy of the means provided, and regardless of his belief in and desire to follow the principle of back-pressure regulation of cut-off, he soon gives it up.

In addition, on modern locomotives, under existing conditions of operation, the engineman has not the time constantly to follow such an absorbing duty in addition to those already imposed upon him.

Confronted with these limitations and at the same time appreciative of the ultimate possibilities of practical application of the theory described, there has been developed and put into successful operation a mechanism for installation on the engine, actuated and responsive to back pressure, which without effort on the part of the engineman provides the locomotive with a self-regulating means of adjusting cut-off to constant back pressure. This device is so designed that at will the engineman may set the engine to operate at any one of three back pressures, the purpose of this being to provide for locomotive operation subject to three of the four conditions cited by Mr. McBride.

In operating a locomotive with this device the engineman, for maximum power, turns a lever to that back-pressure index established for maximum capacity. For medium power a pressure lower than the maximum is obtained by the engineman's turning to the equivalent setting, and for light power, a pressure setting less than that for medium.

There are in service in this country a considerable number of locomotives employing the mechanical device above described, which virtually adjust their own cut-off instantly to existing conditions of speed, load, and steam-admission pressure.

Operation of these engines has resulted in very interesting data as to the possible improvement in economy and capacity to be obtained on existing locomotives.

One instance of an operating division has shown that under identical operating conditions, with 93 per cent of the engines equipped to regulate their own cut-off, the 1000 gross ton-miles per hour were increased 30 per cent with practically the same gross tons per train. In this instance the capacity of the engine was utilized in speed.

In another instance, with a locomotive operated with this device over a 30-mile division, having the same train back-hauled for hand-operation test, and all operating conditions identical, a fuel performance with one engineman of 140 pounds of coal per 1000 gross ton-miles, as against 120 for the machine, was obtained. Another similar test showed 118 pounds of coal per 1000 gross ton-miles for the machine as against 132 for hand operation by the engineman. This is an instance of utilizing the machine purely for fuel saving with tonnage, time, and all other conditions being the same.

In some recent tests on another railroad where the same locomotive was operated over the division by various enginemen in hand operation, alternating with machine operation, an average saving in coal of over 20 per cent per 1000 gross ton-miles was shown in favor of the machine.

These economies are not surprising as it is recognized by railroad operating officials that there is easily a difference of 10 to 20 per cent between the performances of their best and their average enginemen, and a greater difference between their best and their poorest. If a machine did no more than operate all locomotives as good as the best engineman, there would be a considerable element of economy.

It must be further recognized that generally in freight service every-day train loadings are not those established by test, or by what the best engineman can handle, but are nearer the tonnage which can be safely taken over the railroad by the poorest engineman.

The following statements were made by A. W. Bruce, Designing Engineer of the American Locomotive Company, before the Western Railroad Club:

> A railroad is nothing more than a commercial manufacturing plant, the only product of which is transportation, and in which the locomotive is the only direct revenue-producing unit.
>
> The writer realizes perfectly the enormous amount of capital represented in motive-power equipment. What other manufacturing industry, however, could be carried on competitively, using continuously machines twenty to twenty-five years old in the manufacture of its product?

Mr. Bruce's statements are very significant, and to them may be added the thought that the locomotive, which is the productive earning unit of the railroad, is still operated, so far as steam utilization is concerned, by manually controlled rule-of-thumb methods. It is not unreasonable to suppose that elimination of the personal equation by mechanical means should be as proportionately economic in this field as it has been in many others.

W. E. Symons.[3] Although ready at any time to defend the modern equipment of the American railroads, particularly our locomotives, the writer is perfectly willing to admit that efficiencies are not as great as they might have been had certain details been given the attention they deserve. One in particular is back pressure on the pistons. There are thousands of locomotives running today with back pressures on the pistons of from 8 to 15 lb. which should be running with less than 6, and some less than 5—around 4. The effect is equivalent to the sticking of brakes, and the resultant loss of power has cost the railroads of this country vast sums of money. This effect can be eliminated and without putting back-pressure gages in the cab. Although they are splendid indicators, why apply some special device at a considerable expense to remedy a thing that we know exists and for which there is a plain, common-sense remedy without these special gages in the cab?

The writer has ridden on a four-cylinder locomotive representative of common European practice, at a speed of 100 kilometers (about 62 miles) per hour. This engine was equipped with a double valve gear so as to permit adjustment of the admission of the steam to the cylinders and also to control the back pressure of the pistons. By a slight change in the valves controlling the exhaust steam from the low-pressure cylinders, and without admitting an ounce more of steam from the boiler, the engine accelerated from 15 to 20 miles in speed. That is a fair indication of what can be done with American locomotives.

A ten-wheel locomotive built by the American Locomotive Company, reputed to have attained a speed of 120 miles per hour, had a back pressure on its pistons of less than 5 pounds. If the pressure had been as great as in the average passenger locomotives in America it would never have made more than 80 miles per hour, and probably less. It is difficult to understand why, with all the ingenuity that has been brought to bear in designing locomotives and purchasing saving devices, that engineers have not applied themselves more diligently and effectively to facilities for regulating the exit of the steam from the cylinders.

A. I. Lipetz.[4] The writer regrets that he cannot agree with Mr. McBride's theory as to back pressure and cut-off adjustments, although it must be admitted that the now popular trend of equipping locomotives with back-pressure gages can be of a practical value in some instances.

[4] Consulting Engineer, American Locomotive Co., Schenectady, N. Y., Non-resident Professor of Locomotive Engineering, Purdue University, Lafayette, Ind. Mem. A.S.M.E.

In order to make clear the remarks which follow, several mass diagrams of results obtained from Altoona tests with the well-known I1s locomotive of the Pennsylvania Railroad will be

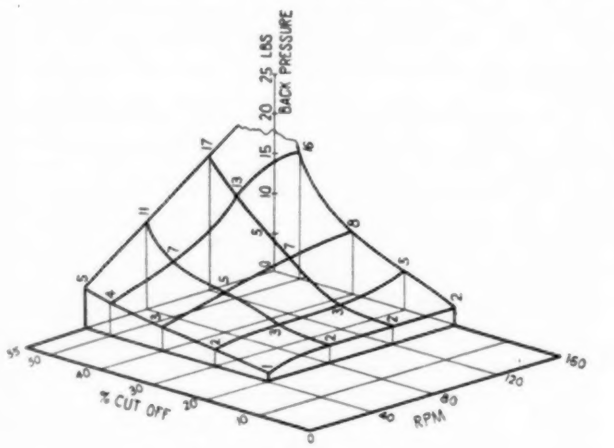

Fig. 2

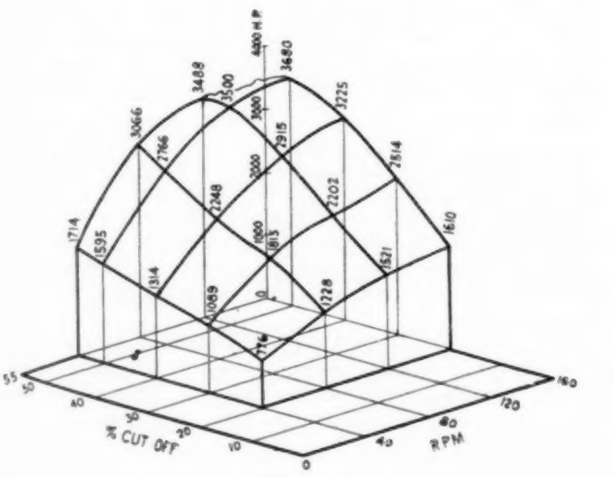

Fig. 3

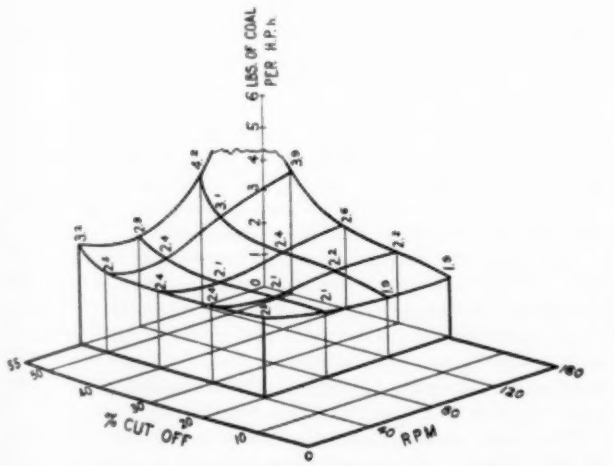

Fig. 4

presented. These tests were chosen for the reason that Mr. McBride refers to them in his paper, although the writer prefers a more modern locomotive than the I1s. The mass diagram of Fig. 2 shows the back pressure as a function of both cut-off in per cent of stroke and speed in revolutions per minute. Fig. 3 gives the indicated horsepower of the locomotive in relation to the same two variables. Fig. 4 shows the fuel consumption in pounds per indicated horsepower-hour. The three mass diagrams refer to full throttle opening. It can be seen that the back pressure goes up slowly with the speed at short cut-offs, and with the cut-off at low speeds, but as both speed and cut-off increase simultaneously the back pressure goes up very rapidly—this resulting in a surface of a more or less hyperboloidal form. As regards the horsepower the variation is reversed. It is more pronounced at low speeds and short cut-offs and drops down as both speed and cut-off go up, resulting in a surface of an ellipsoidal form with a distinct maximum value. The consumption of fuel

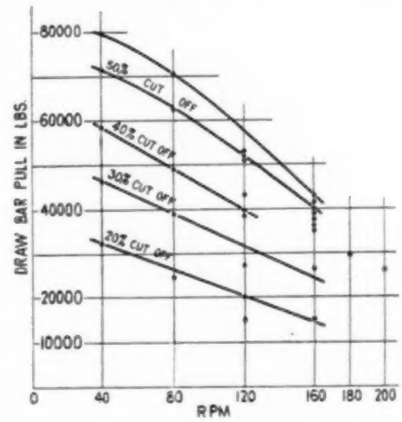

Fig. 5

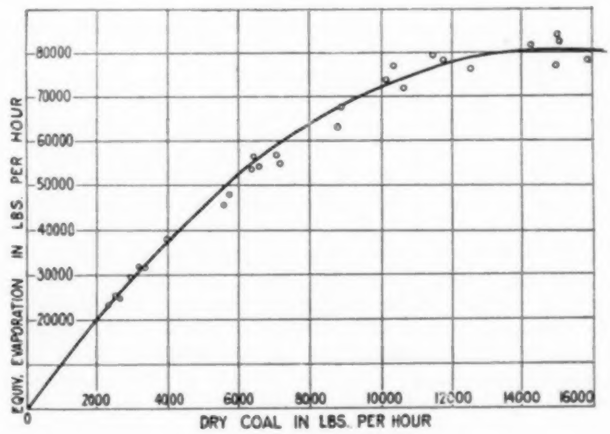

Fig. 6

is more or less uniform when the horsepower is low, but increases rapidly with the increase of output.

Two ordinary charts also are shown which give the variation in drawbar pulls in relation to speed (Fig. 5), and the equivalent evaporation of water as a function of the amount of coal burned in the firebox (Fig. 6). They are taken from Test Bulletin No. 32 of the Pennsylvania Railroad. All the mass diagrams and charts refer to sustained conditions of locomotive performance.

By comparing the figures shown in the mass diagrams it can be seen that in one case an output of 3500 horsepower can be obtained at 50 per cent cut-off and 120 r.p.m.; the back pressure will then be 13 lb. per sq. in. (all pressures above atmosphere). As can be seen from the accompanying chart, the engine under these circumstances will develop a drawbar pull of about 52,000 lb. If the train tonnage and profile are such that this exceeds

the train resistance, the speed of the locomotive will go up, and if it should reach 160 r.p.m., the power developed at the latter speed will be 3680 horsepower and the back pressure will go up to 16 lb. per sq. in.; the fuel consumption also will change from 3.1 to 3.9 lb. of coal per indicated horsepower. Such a performance may not be considered economical, but disregarding for a moment the thermal efficiency of the locomotive, it will be seen that a greater horsepower was obtained at a higher back pressure and, consequently, a back pressure of 16 lb. per sq. in. must be allowed, if such a speed on a grade is required.

On the other hand, suppose that when the engine is developing a drawbar pull of 52,000 lb. with 50 per cent cut-off at 120 r.p.m. the grade changes and the engine driver may wish to retain the speed. If he should attempt to increase the cut-off to 55 per cent, the back pressure will go up from 13 to 17 lb. per sq. in., reaching probably 16 lb. per sq. in. at somewhere between 50 and 55 per cent cut-off. But as can be seen from the mass diagram he can gain nothing from that as the power remains almost constant and, as the tractive effort has gone up, the speed will drop. It can be seen, therefore, that the back pressure is a function of the combination of cut-off and speed, and it cannot be stated that the maximum power is obtained at a constant back pressure for all speeds.

It is true that the back pressure at maximum power varies very little. This is simply due to the fact that when the locomotive approaches its maximum output the possibility of varying speed and cut-off becomes very slight. A locomotive does not develop its maximum power at low speeds no matter how big a cut-off is used. Neither does it develop its maximum power at high speeds with short cut-offs. The engine will therefore most of the time have a back pressure of 3 to 7 lb. per sq. in. Maximum power is obtained only when both long cut-offs and high speeds are used, and consequently the back pressure must be near the maximum and cannot vary greatly. This may lead to an impression that the back pressure is constant at maximum power, but, as has been shown above, it cannot be considered so.

The above-mentioned 16-lb. back pressure permitted burning $3.9 \times 3680 = 14{,}352$ lb. of coal per hr., or, as the grate area of the locomotive is 70 sq. ft., 205 lb. per sq. ft. per hr. Such a rate of firing is very wasteful, and it would be more advisable to reduce it to 100 lb. per sq. ft. per hour, or even less, in order to obtain higher boiler efficiency (see equivalent evaporation chart). Then, if a *maximum* back pressure of 7 lb. per sq. in. is ruled, the engine driver may choose between two combinations—50 per cent at 80 r.p.m., and 40 per cent at 120 r.p.m. The back-pressure gage will give him no indication as to which of these two combinations to use, but an experienced driver will choose in accordance with requirements of traffic—tractive effort and speed. In one case he will get higher drawbar pull; in another, higher speed and power, although the back pressure remains unchanged.

The limitation of back pressure to 7 lb. per sq. in. means in this case only that the tonnage and speed should be such as to require no more than 2915 horsepower. If the train is heavier, or the time table requires higher speed, the driver will have to go to higher back pressures.

This reasoning applies, as stated above, to sustained conditions of locomotive performance. Performances corresponding to those given by the diagrams may go on indefinitely, but it is possible for short periods to overload the locomotive and to make use of a portion of the heat energy stored in the hot water in the boiler. The steam pressure may for a certain period of time remain unchanged, but the water level will drop. For short distances this can be permitted, and then higher cut-offs at higher speeds can be used and still higher back pressures will be obtained without doing any harm to the locomotive. While it is true that this may result in consumptions of fuel of over 4 lb. of coal per i.hp-hr., this will not amount to much if the periods are short, and it may still be more economical for operation over the whole division to overload the locomotive over a short stretch of track. The *constant*-back-pressure theory would do harm in such a case, but the *maximum* pressure indication may be of some practical value. This can be determined only by experience or special tests.

If, however, the engine driver should tax the boiler still heavier, a drop in boiler pressure will take place and the conditions of locomotive performance will become unstable. The drawbar pull will correspondingly drop and the storage capacity of the boiler will soon become exhausted. This should never be attempted in proper handling of a locomotive, but it happens very often when a heavy train is too rapidly accelerated from rest to a high speed, just before a heavy grade, and stalling of the locomotive results. These are the tests which were made by Mr. Retterer to which Mr. McBride refers, and the practical value of his conclusions is that such manipulations should not be permitted, and in order to avoid them back-pressure gages should be used. This is quite a different matter and cannot be corroborated by referring to Altoona tests which were made entirely on a sustained-operation basis. The same purposes can be served by watching carefully the steam gage, or the speed indicator, but a back-pressure gage may give a more timely warning to the inexperienced engine driver. It cannot be, though, of such universal service as described in Mr. McBride's paper.

H. B. Oatley.[5] It is, of course, well-known that through the use of feedwater heaters, as well as exhaust-steam injectors, a portion of the exhaust steam is utilized for the feedwater heating. The effect in the locomotive cylinder, therefore, is that of a partial condensing operation and results in a very desirable decrease in the back pressure on the pistons through the entire range of operation.

In considering the reduction of back pressure, although it is not suggested in the paper, there is an opportunity for improvement in providing ample exhaust passages. This is a feature that is, of course, well known to the locomotive designers, and a great deal of progress has been made in recent years. In this same connection, the query has often arisen as to why steam-chest valves might not be made with double exhaust ports. There is much less difficulty in getting the steam into the cylinder than there is in getting it out, and it would seem that the double-ported exhaust valve should have advantages of moment as a means of reducing the back pressure.

The Author. Mr. Pearce, in his discussion, accepts the theoretical soundness of the use of back pressure to secure proper adjustment of the cut-off, but advocates a mechanical device to set the cut-off rather than dependence on the engineman and his attention to the back-pressure gage.

The paper was intended primarily to establish the principles involved and considered the back-pressure gage as a means through which these principles could be put into effect. Without doubt a mechanical device could and would adjust the cut-off more promptly and more accurately than could the engineman depending on the gage, but whether the mechanical device or the gage will be the better will doubtless develop with time.

The results obtained from the mechanical device as reported by Mr. Pearce in his discussion are certainly an endorsement of the general principle of the use of back pressure either to adjust

[5] Vice-President, in Charge of Engineering, The Superheater Co., New York, N. Y. Mem. A.S.M.E.

or to indicate the proper adjustment of the cut-off and its possibilities.

Mr. Symons, in his discussion, considers back pressure from the standpoint of the designer of the locomotive, a most important item mentioned in the first paragraph of the paper. Considered from this standpoint the back pressure should be as low generally as proper combustion of the fuel will permit; the back-pressure gage can be of little value, and Mr. Symons naturally concludes that there is no need for it. However, after the locomotive has been properly designed and turned over to the operator, the back pressure can then be used as a valuable assistance in operation. While, therefore, the importance of a low back pressure generally, as a matter of the design of locomotives is fully appreciated, the paper treats of an entirely different subject; that is, of the subsequent use of a specific back pressure in the operation of locomotives under certain operating conditions.

Mr. Oatley raises the question of the area of the exhaust ports, which is quite pertinent since any increase in area of exhaust ports would very probably lower the particular back pressure indicating maximum cylinder power, and also result in a slightly greater maximum cylinder power. However, the larger cylinder ports would not in any way interfere with the use of back pressure to indicate the proper adjustment of the cut-off for maximum cylinder power, but merely result in the use of a lower back pressure as the indication of that power.

Mr. Lipetz has submitted a very valuable contribution and does not agree with the author's conclusion. Unfortunately, however, he has used data from tests of a quite special locomotive, which tests were conducted only under conditions 1, 2, and 3 listed in the paper, whereas it is demonstrated in the paper that back pressure as an indication of proper adjustment of the cut-off can be of use only under condition 4; that is, where maximum cylinder power is desired. It is only natural, therefore, that Mr. Lipetz, because of the test data he has used, should not reach the same conclusion.

The quite special locomotive, the test figures of which were used by Mr. Lipetz, was designed for a special purpose which it has accomplished, but not for speeds high enough to develop the maximum power from its very large cylinders. Had this locomotive been designed for and tested with longer cut-off or higher speed or both and thus been representative of practically all other of our locomotives, then Fig. 3 submitted by Mr. Lipetz gives a good idea of what would happen. From the general trend of Fig. 3 it is evident that when extended to higher speed and longer cut-off, the top surface of the figure must flatten out at a level slightly under 4000 horsepower. Fig. 3 therefore demonstrates that slightly less than 4000 horsepower is the maximum power that can be obtained from these particular cylinders at any combination of cut-off and speed. Fig. 3 therefore confirms the author's Fig. 1 in its demonstration of the fact that the power that can be obtained from any particular cylinder, nozzle, and steam pressure is limited to a certain definite maximum. The back-pressure gage indicates when this maximum has been reached. When properly used the back-pressure gage prevents attempts to obtain more power than this maximum, i.e., the use of too long a cut-off with the consequent waste of steam and fuel, and also assures that this maximum will be obtained when desired because of its indication of the cut-off that should be used to obtain it.

The locomotive from which the test figures used by Mr. Lipetz were taken comes within the reservation made in the paper to the effect that "with the same back pressure more power is developed at higher speed and shorter cut-off," and in this differs from the locomotive the test data of which were used in plotting the author's Fig. 1. However, an investigation of the test data of the special locomotive indicates that "the maximum power for each speed is obtained at one and the same back pressure, and the usefulness of back pressure indication of proper cut-off to obtain maximum power is not lessened."

Fig. 1 of the author's paper was plotted from test data obtained from test of the Pennsylvania Railroad Mikado L1s. It is acknowledged that the L1s is not as modern a locomotive as the I1s but it is believed that the L1s well represents the majority of freight locomotives in this country and also all passenger locomotives as far as back pressure and cut-off adjustment for maximum cylinder power are concerned.

Present-day tendencies are leading more and more toward the more frequent requirement of maximum power from the locomotive. With the back-pressure gage or its equivalent and the consequent assurance that maximum cylinder power can be immediately and accurately obtained when required, locomotives will be loaded and speeded to a point where maximum cylinder power will be required of them even more frequently, and the need for the back-pressure gage or its equivalent will become more pronounced.

The author appreciates the valuable discussion which has been submitted and hopes that the paper, together with this discussion, will lead to a further study and a better understanding of the use that evidently can be made of back pressure to secure maximum cylinder power when desired, and that without waste, with a still greater increase in the efficiency of locomotives and their utilization.

# Heating and Ventilating of Passenger Cars

## The Need for Larger Steam-Heat Connections Between Cars in Long Trains; and a Description of the Automatically Controlled Vapor System of Car Heating

By EDWARD A. RUSSELL,[1] CHICAGO, ILL.

IN THE earlier years of passenger-car construction, little attention was given to car insulation or to the leakage of air through the crevices around windows and doors. These conditions permitted a natural ventilation by means of air currents which increased with train speed.

Today the improved steel-car construction (including effective insulation, elimination of crevices around doors and windows, and, in certain territories, the general use of double windows) has materially reduced the volume of air naturally changed even under high speed. These improvements in car construction, brought about in the interest of economy and comfort, make artificial ventilation necessary.

All exhaust ventilators now in use vary in capacity according to train speed. This variation is admittedly too great as between a car at high speeds and one standing still. It is also a fact that in passenger cars, even at reasonably high speeds, there will be "dead-air" spots, generally about midway between floor and deck, and at either side of the aisle, in an open-body car. The regulation of the exhaust capacity and the maintenance of a continuous and uniform change of air throughout the car, regardless of train speed or of wind direction and velocity, would result in increased comfort and economy.

The number of ventilators to be applied to a car should be determined by the capacity of the ventilator and the maximum number of occupants to be carried. The Master Car Builders' Association report and recommendations in 1908 showed that 1000 cu. ft. of fresh air should be supplied per hour for each passenger.

The present overheated and stuffy condition often present in cars standing at stations, can best be overcome by an arrangement whereby steam will be automatically shut off and a forced ventilation simultaneously begun whenever cars come to a stop. This could be further developed so that the amount of forced ventilation would be automatically controlled by train speed.

An efficient ventilation and heating system requires sufficient fresh air admitted by proper intakes, uniformly warmed by an easily regulated or automatically operated heating system, thoroughly circulated for the comfort of occupants, and exhausted by properly regulated mechanical means.

The heating of passenger cars has recently received special attention because of the difficulties that have been introduced by the advent of larger locomotives and the hauling of very long passenger trains. The increase of steam pressures necessary for car heating has rendered rubber hose unsatisfactory and uneconomical for steam connections between cars. Where rubber steam hose is used, a maximum of ten to twelve cars can be satisfactorily heated. In severe weather it is the practice on some roads to remove the steam hose, particularly on head-end cars, at the end of every trip and replace it with new hose, in order to avoid train delays due to burst steam hose.

A most timely editorial appeared in *Railway Age*, January 8, 1927, entitled "Car Heating Both Difficult and Expensive," in which it was stated that "tests have shown that a modern steel passenger car can be heated with about 2.85 pounds of steam per hour per degree difference in internal and external temperatures. This difference may reach 75 degrees or more, and in a 15-car train, therefore, 3200 pounds of steam per hour are required, or roughly eight per cent of the locomotive boiler capacity... A passenger car is essentially a room on wheels with a large proportion of window area, and exposed on all sides; and passes at high speeds through blizzards and sleet storms, and all kinds of inclement weather."

At the close of this editorial this very significant statement was made: "The flow of steam through two-inch pipe in train line is restricted in most cases, owing to the use of couplings between cars with only $1^3/_8$-inch openings."

In a later editorial (March 12, 1927), on "Heating Long Passenger Trains," it was stated that "with a maximum train-line pressure of 130 lb. at the reducing valve, it has been found impossible to heat the rear cars of a 15-car train to anywhere near 70 degrees. Under these conditions, it has been found necessary to have the initial train-line pressure materially higher to supply steam fast enough to be carried back to the rear car of such a train. The utilization of high steam-line pressures presents a number of difficult problems in design, maintenance, and operation that can only be solved by considerable study and experiment."

These two editorials indicate the problems that have to be met in car heating.

### Car-Heating Requirements

Essentially there are three requirements for ideal passenger car heating:

1 Sufficient volume and pressure of steam supply from locomotive for the adequate heating of every car in train;

2 Full-area steam passage through connections between cars, with minimum friction and freedom from leaks; and

3 Correct amount, distribution, and regulation of heating surface in each car to heat the car economically and satisfactorily under all conditions.

### Locomotive Equipment

For a number of years a 2-in. steam train line has been used under passenger cars, but the source of supply from the locomotive boiler is still restricted to a $1^1/_2$-in. outlet at the stop valve, with even smaller area for steam passage through the valve. This restriction necessarily retards the volume flow of steam to meet car-heating demands in severe weather, particularly on long trains. The use of a 2-in. stop valve, preferably of the angle type, constructed so that the valve seat lifts free from the path of the steam, will provide a greater amount of steam for car-heating purposes.

Essentially, then, this area should be maintained in reducing-valve connections in all steam-heat piping on the engine and in all steam-heat connections between engine and tender. Tests made by one of the large railroads, using a 2-in. stop valve and a 2-in. pipe to reducing valve, showed pressures at the reducing valve more than 10 per cent higher than those where a $1^1/_2$-in. stop valve and pipe were used with the same boiler pressure. It is important that the full area be obtained at the boiler outlet

FIG. 1 VARIATION IN STEAM PRESSURES AT DIFFERENT PARTS OF A TWENTY-CAR TRAIN WITH 2-IN. AND $1^1/_2$-IN. CONNECTIONS

to the steam-heat line, and that the steam-heat piping on the locomotive be properly protected with covering.

Of more importance than is often recognized is the pressure-reducing valve used in the steam-heat line on locomotives. The length of train and varying outside temperatures determine the pressure and volume of steam required for car-heating purposes. Considering the maximum steam requirements for car heating—possibly eight per cent of the boiler capacity—it is important that the reducing valve should permit economy in steam consumption under other than the maximum requirements. The pressure-reducing valve, therefore, should be capable of adjustment to any desired pressure, and should maintain that pressure without fluctuation. A most important feature in the operation of locomotive pressure-reducing valves is the item of maintenance cost and the delay to the locomotive while making repairs; this has been successfully overcome by the adoption on many roads of a reducing valve so constructed that the cylinder walls and piston (the principal parts which wear or "wire-draw") may be quickly renewed without removing the valve from the pipe connections.

With present pressure requirements on steam-heat lines, rubber steam hose cannot be successfully used between the engine and tender and at the rear of the tender. Tests conducted in 1920 by the Montreal Air Brake Club showed a pressure loss between the reducing valve and the rear of tender of 13 per cent with standard $1^1/_2$-in. steam hose between engine and tender, and a pressure loss of 5 per cent with 2-in. metallic connections. Flexible metallic connections for this service should adapt themselves to any motion in service without restricting the steam areas.

With locomotives thus equipped, including all 2-in. piping and connections on tender, a higher pressure is available for car-heating purposes.

## CONNECTIONS BETWEEN CARS

The necessity for a full 2-in. steam passage through end valves, metallic conduits (used instead of rubber hose, which is not practical for high pressures), and couplers between cars has been proved by numerous tests.

As far back as 1922 it was demonstrated in actual service tests that when changing engines at terminals, steam would pass to the rear of a train equipped with 2-in. connections between cars in less than one-half the time required in a train equipped with $1^1/_2$-in. connections between cars.

Last winter, one railroad, in an effort to heat long trains of eighteen to twenty cars, removed the reducing valve from the locomotive and applied armored steam hose to all cars so that full boiler pressure would be available for car heating; but even with this arrangement the rear cars could not be heated in severe weather. Two-inch end valves and 2-in. metallic conduits were applied, leaving the $1^1/_2$-in. couplers which have only a $1^3/_8$-in. gasket opening. However, to heat the rear cars satisfactorily in extreme weather it was found necessary also to apply 2-in. couplers.

Another recent test indicated a pressure drop through the equivalent of five cars equipped with $1^1/_2$-in. end valves, rubber hose, and couplers which was 50 per cent greater than with the 2-in. connections between cars.

It has been found, where 2-in. metallic conduits are applied, that the saving in cost of steam-hose renewals over a period of two heating seasons in northern climate will more than cover the entire expense of the metallic conduits. Further maintenance economies will result from the use of metallic conduits constructed so that the gaskets and any other parts requiring renewal can be changed without special tools and without removing the conduits from cars; and by the use of gaskets with long life—made possible by arranging the conduit so there is no weight or strain on the gasket under any condition of service.

One railroad made a very exhaustive test last winter, with twenty cars standing in yards and with fifteen cars in train service, to compare the results obtained by using $1^1/_2$-in. connections (end valves, rubber hose, and couplers) and 2-in. metallic connections between cars. Fig. 1 and Table 1, compiled from this test, show conclusively the desirability of equipping locomotives and passenger cars with 2-in. steam-heat connections throughout.

A 2-in. end valve is necessary, particularly on long trains and end valves should have full-area unrestricted ports for

steam passage; should be easily and quickly operated against high pressures, and constructed to automatically hold the valve in open position to prevent train-line pressures closing the valve while in service.

Steam couplers should also be of 2-in. size and should be made with straight port through connected couplers. A positive locking arrangement (preferably with yielding tension to compensate for gasket wear) is necessary, and 2-in. couplers must interchange and lock with the present $1^1/_2$-in. couplers to permit their being operated with the present couplers during any period of transition to the 2-in. coupler as standard.

### Radiating Surface in Cars

Steam as a medium for heating passenger trains possesses many advantages over other methods, such as the hot-water circulating system or the electric heating system. In comparison with a hot-water system, the weight to be carried with a steam system is almost negligible; and steam has a decided advantage over hot-water in the matter of initial cost and maintenance expense. Another important feature in favor of the type of steam heating system generally used is that there is no danger from injury to employees or passengers in case of accidents which might break the heating pipes.

There is, of course, a special field for electric and hot-water heating systems. In strictly suburban service electrically operated cars are heated by electricity, although an electric heating system is more expensive to operate than a steam heating system. For main-line passenger cars, even where hauled by electric locomotives, the use of steam is far more economical, more flexible in regulation, and more desirable. It is the present practice on practically all railroads operating portions of their lines electrically, to equip electric locomotives (or a special heating tender between the electric locomotive and the first car of train) with a flash boiler of sufficient capacity to supply steam for car-heating purposes.

Of recent years hot-water circulating systems of car heating have been used only for auxiliary heating purposes on such cars as diners, business cars, and a few sleeping cars that are assigned to service where steam is not available at "lay-over" points and where the cars must be warmed for occupancy before the locomotive is attached. The development of self-propelled railway motor coaches on many railroads has increased the use of hot-water systems of heating.

The use of pressure steam-heating systems has been discontinued. They are neither safe in case of breakage of radiating pipes from any cause, nor economical in steam consumption. With pressure systems the cars in the head ends of trains were always overheated, and the traps were frequently frozen. While steam under pressure has a higher temperature, the difference is of no advantage in comparison to the objections and troubles arising from the use of pressure heating systems.

### Vapor System

The most universally used system of car heating today is the vapor system. The vapor system consists of a number of properly arranged heating coils inside a car. Live steam taken from the train pipe is admitted after the pressure has been reduced to atmospheric pressure by passing through a vapor regulator underneath the car. The heating pipes inside the car are divided into several independent coils or sections of radiating pipes, the number of coils and the amount of piping

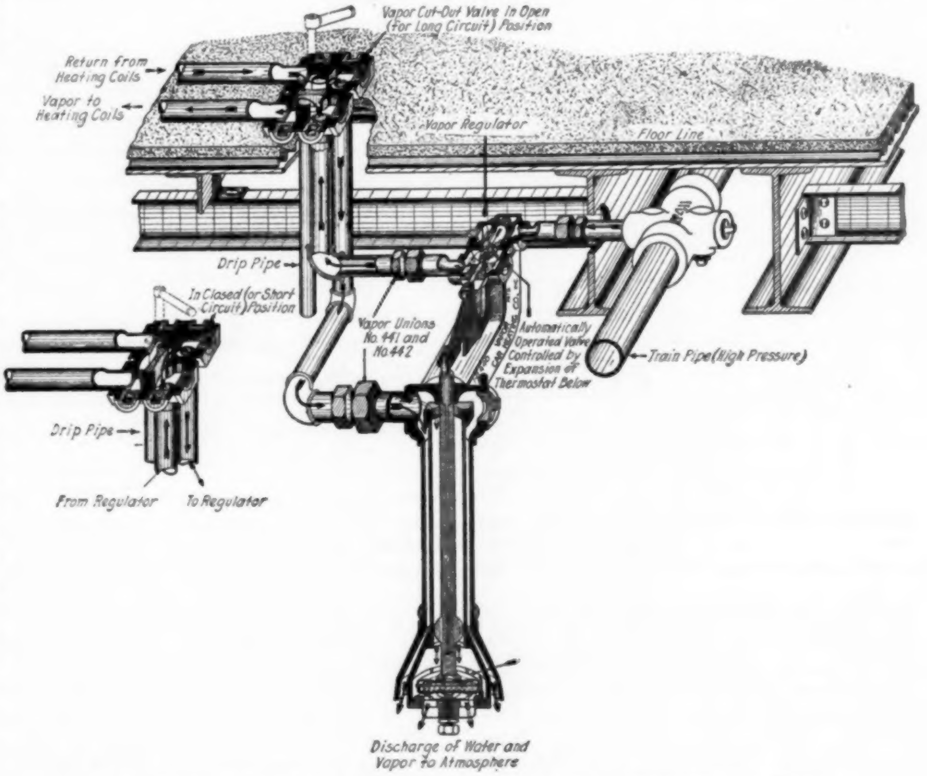

Fig. 2 Diagram of Control and Regulating Valve of Vapor Heating System

being determined by the interior arrangement of the car and its maximum heating requirements. Each coil or section of radiating pipes has a separate and independently operated cut-out valve by means of which, when the valve is open, steam at atmospheric pressure is diverted into its heating coil. The steam or condensate returns from the coil through the valve and back to the vapor regulator; or (if the valve is closed) the steam is bypassed from the valve directly to the vapor regulator, where the expansive diaphragm regulates the admission of steam from train line.

Variations in the temperature of the steam or hot condensate against the diaphragm in outlet of vapor regulator determine the amount of steam admitted from train line through the vapor regulator.

Fig. 2 illustrates the principle of the vapor-system operation. The "short-circuit" feature of the vapor cut-out valve keeps the extreme exposed outlet of the system warm at all times while steam is on the train line, regardless of whether any of the heating coils are using steam. This prevents freezing of the heating system.

With a vapor system, the heating pipes inside the car contain only steam at atmospheric pressure. The outlet of the system is always open to the atmosphere, so that pressure cannot build up in the heating pipes.

The temperature of steam at atmospheric pressure is 212 deg. fahr. at sea level and the heating pipes in all cars equipped with a vapor system are at the same temperature regardless of varying train-line pressures at the head end or rear of trains. The temperature of the steam or condensate at the outlet of a vapor system determines the amount of steam admitted through the inlet of the vapor regulator. A vapor system is thus economical in steam consumption, because only the steam actually required is taken from the steam train line.

In calculating the radiating surface required for a passenger car there are many conditions that must be considered, such as the kind of car, its construction, the tightness of windows and doors, the minimum outside temperatures encountered, and the maximum inside temperature required. There are definite heat losses to be figured. These vary somewhat, depending on methods followed in construction. Formulas for figuring conductivity of walls, floors, etc. of different materials and insulations, were given in a paper by K. F. Nystrom of the C.M. & St.P.Ry. presented at the February, 1924, meeting of the Canadian Railway Club. This paper also indicated the usual heat losses in steel passenger cars.

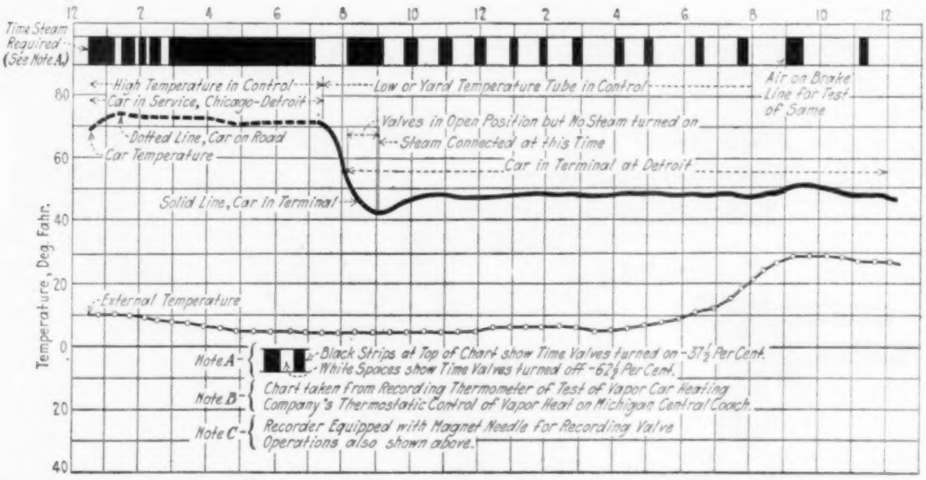

Fig. 3 Comparison From Tests of Steam Required in Service and at Terminal by Car Equipped With Double Automatic-Control Vapor System

(For car in service, valves are on 90 per cent of the time; for car idle, valves are on 23 per cent of the time.)

The total amount of radiating surface required in a steel passenger car is generally based on the ratio of one square foot of heating surface to thirteen cubic feet of space inside the car. This, of course, assumes that the car is properly insulated.

With the required heating surface arranged to permit the use of steam in the heating coils only as necessary to maintain proper car temperatures, correct temperature regulation is easily accomplished either through a manually or an automatically controlled vapor system. In the manually controlled vapor system the cut-out valves (see Fig. 2) for each heating coil are operated by hand.

In an automatically regulated vapor system the cut-out valves are operated electrically from the car lighting circuit, and are thermostatically controlled to admit steam into the heating coils as required to maintain predetermined car temperatures.

A heating system for passenger cars must be arranged to warm the car under all conditions of outside temperature, which, during a single trip on some roads often range from below zero to a point requiring no heat whatever. This necessitates extreme flexibility in methods of controlling inside car temperatures.

This is easily accomplished with the manually controlled vapor system, arranged (in the ordinary steel passenger car) with four separate and independently operated coils or units of radiation consisting of one three-pipe coil and one two-pipe coil on each side of the car. This arrangement permits the use of steam in 20, 30, 40, 50, 60, 70, 80, or 100 per cent of the maximum heating surface provided, and will satisfactorily heat a car under any outside temperature conditions.

The dependence upon the human element to turn steam on or off does not always meet the demand of the traveling public. Furthermore, cars lying over at terminals require heat to protect toilet water, etc. from freezing. The natural consequence is overheating of cars during the "lay-over" period. Improper manual regulation in service and overheating at terminals result in excessive steam consumption for car heating.

### Automatic Temperature Regulation

In the development of automatic temperature regulation for passenger-car heating the paramount consideration has been its resulting economy to the railroads. Normally a passenger car is in train service only one-third of the time. On some roads the average is more, and on some roads less. It is therefore important to avoid all unnecessary waste of steam by the usual overheating of cars lying over at terminals approximately two-thirds of the time.

There is no necessity for maintaining in cars in terminal yards the temperatures required in service. A 50-deg. car temperature in yards will prevent freezing of toilet water and permit cleaning and other work inside the car without discomfort. Such temperatures can be maintained at terminals by automatic temperature regulation.

To maintain by automatic means a temperature of 50 deg. in cars in terminals for two-thirds of the time, and, say, 70 deg. in service for one-third of the time, requires the use of two thermostats, each made to operate at the predetermined temperature, one for terminal control and one for service control.

The requirements of an automatically regulated vapor system are as follows:

It must retain the "short-circuit" principle of the manually operated vapor system in order to prevent freezing, etc.

It requires a double thermostat properly located in the car.

It must be designed to change automatically from the 50-deg. terminal-control thermostat to the 70-deg. service-control thermostat, or vice versa, without any manual attention. This is accomplished by the use of an air-operated contact switch, arranged so that the presence of air in the brake train line will put the 70-deg. or service thermostat in control of the heating system, while the absence of air in the brake line will put the 50-deg. or terminal thermostat in control.

It must be arranged so that the 70-deg. thermostat can be put in control manually when it is necessary to heat cars for occupancy and there is no air in the brake line, at the same time not affecting the automatic change from 70 to 50 deg., or vice versa, when air has again been connected to brake line.

It must have a valve mechanism which will not consume electric current constantly in either the open or closed position, and provision must be made for manual operation of the valves in case of failure of the car lighting current at any time.

The thermostats, magnetic valves, etc. must be protected

from damage by accidental excess voltage through wiring connections.

With the possible maximum use for car heating of 8 per cent of the total steam generated by the locomotive, it is very essential that every economy be made in heating passenger trains. An automatically regulated vapor system will maintain uniform temperatures in train service, increasing the comfort of traveling public, and will effect considerable economy in actual steam consumption. It will also eliminate unnecessary waste of steam in heating cars at terminals.

Fig. 3 shows the result of a 24-hr. test, both in service and at the terminal, of one car equipped with an automatically regulated vapor system. It will be noted that in service, with an average outside temperature of 6 deg., a uniform temperature was maintained in the car and steam was actually shut off automatically for 10 per cent of the time. In the terminal, steam was shut off 77 per cent of the time.

The saving in steam and coal consumed in heating passenger cars at terminals is further emphasized by a test made at a Chicago passenger yard of two 70-ft. steel passenger coaches, identical in construction and in the arrangement and amount of radiating surface, quoted below:

Both cars had arrived in the same train, and inside temperatures were the same at beginning of test.

Ventilators of both cars open; vestibule doors adjusted similarly; temperature readings taken, and all condensation measured at frequent and regular intervals.

Steam supplied both cars from same source, through a tee-connection.

| | Automatic-control car | Uncontrolled car |
|---|---|---|
| Outside temperature, 26 deg. fahr....... | .... | .... |
| Average inside temperature maintained during "lay-over," deg. fahr... | 53 | 83 |
| Percentage of time steam was used in radiating pipes.................... | 18 | 100 |
| Average condensation, lb. per hr....... | 33.35 | 124.76 |
| Average saving condensation, lb. per hr.. | 91.41 | |
| Or approximately.................... | 14 lb. coal per hour | |
| Total saving per car per year......... | 40,000 lb. (20 tons) coal | |

Also approximately 37,000 gal. of water.

(Above total saving based on the fact that passenger cars lie over at terminals or in yards practically two-thirds of the time, and allowing 188 days out of each year during which steam would be required in yards.)

Condensation from yard line drained before steam entered either car.

One car operated continuously under double automatic control vapor system, with the 50-deg. or "lay-over" thermostat in control.

Other car, similarly equipped, had the automatic control feature cut out, and was operating continuously with all valves in the "On" position or wide open, the usual way of heating "lay-over" cars.

In spite of numerous tests that have been made to determine the actual or average steam consumption required to heat passenger cars both in train service and at terminals, it may be said that no formula has been developed that will be accurate under all conditions.

Theoretically, approximately three pounds of steam per car-hour will be required for each degree of temperature difference to be maintained between outside and inside for an ordinary steel passenger car.

The diversity in types of car, their methods of construction and insulation, interior arrangements, number of exposed outlets of heating system, direction and velocity of wind, all affect the condensation of steam for car heating.

An important factor is the speed of train which automatically increases the amount of air exhausted through ventilators. As an indication of the relative increase in condensation with increased speed of train, note the following result of test made:

| Outside temperature, deg. fahr. | Pressure at steam-heat gage, lb. per sq. in. | Pressure at rear of 11th car: at 40 m.p.h., lb. | at 60 m.p.h., lb. |
|---|---|---|---|
| 27 | 110 | 40 | 30 |
| −8 | 110 | 30 | 15 |

The automatically regulated vapor system is also of considerable advantage in maintaining or periodically building up train-line pressures. During a test of a train (all cars equipped with automatically regulated vapor system) it was found that as the thermostats in cars automatically closed the admission valves and cut out steam from the heating coils inside the cars, train-line pressures increased. In one instance, presumably the result of thermostats in all cars shutting off steam about the same time, the pressure at the rear of the last car increased 25 pounds in ten minutes.

Proper insulation of all exposed piping and connections underneath the car will of course, aid the reduction of condensation in severe weather and at high speeds.

## Discussion

P. D. Mallay.[2] Last winter the writer made a rather extensive run on a train of test cars to determine the exact amount of steam which would be required to heat trains of varying length at different speeds under different weather conditions. One very noticeable fact was that for a train running under severe weather conditions at a speed of from 40 to 50 miles an hour, more than twice the available radiating capacity of the heating system was required to heat a car. It seemed that the following conditions might cause apparent loss of steam:

When the steam leaves the locomotive it passes through a reducing valve and then through the tender connection and in succession through the couplings between the cars. In most cars the opening in the coupling is 1 in. in size, the steam then expanding again into a 2-in. train line. It was observed that in passing over track pans the test steam flow in the test car dropped appreciably. After the pan was passed conditions reached nearly equilibrium, and the flow rose to normal. Those rides indicated that there were four important factors in the consumption of steam for heating purposes, as follows: (1) The major losses in throttling valves on the locomotive; (2) periodic throttling through the car couplings; (3) the production of eddy currents in joints of different types; and (4) losses due to radiation of the train line under the cars.

In trying to correct conditions it was found with some surprise that it was not economic to increase the thickness of the insulation on the lines to more than 1 in. The fact that the steam flow dropped considerably in passing over track pans led to the conclusion that one of the greatest factors of loss was condensation in the steam connections, and that naturally led to the assumption that they would have to be insulated. Can they be insulated? and if so, how? If the author's observations have been such as to lead him to conclusions different from those just recorded, his comments should add greatly to the value of the paper.

H. B. Oatley.[3] The Long Island Railroad has been using superheated steam for train heating for a number of years, and has reported some very satisfactory results both as to the saving in fuel on the locomotive and in the more constant heating of the cars. It is reported that the railroads in the Northwest, particularly those roads operating with the extremely long transcontinental trains containing as many as 15 or 18 cars, operating

[2] Office Manager, Railroad Department, Johns-Manville (Inc.), New York, N. Y. Jun. A.S.M.E.

[3] Vice-President in Charge of Engineering, Superheater Co., New York, N. Y. Mem. A.S.M.E.

as they do through the extreme low temperatures of the winter, down to 30 and 40 deg. below zero fahrenheit, have been considering its use. It is believed that they can heat the entire train by using superheated steam on the train line and avoid the necessity of using individual car-heating equipment in the last four or five cars of the train.

In that connection the question has come up of whether or not the rubber hose connections between cars would stand the higher temperatures of superheated steam. Some of the roads are using metallic connections, but the Long Island apparently is using the rubber hose. It is difficult to figure a thermal gain by using superheated steam—heating is simply a question of transferring heat units—but the argument in its favor is that steam can be forced back further in the train because condensation does not take place as quickly as with saturated steam, and therefore a given size of heating line ought to carry the heat further.

H. W. Fitch.[4] Information from Mr. Russell on the extent to which superheated steam has been used for car-heating should prove valuable.

G. M. Eaton.[5] Quite often a question arises as to the quantity of energy required to heat a train of cars with steam generated electrically, and the following may be interesting. A good many years ago when the Pennsylvania was considering electrification from Manhattan Transfer to New York, a test was run on an electric train-heating boiler installed on an electric locomotive. Operating on the West Jersey & Sea Shore in zero weather with a full-capacity train, as the writer recollects it, the records showed that the boiler required about the same energy to heat the entire train that the locomotive required for hauling the train.

# The Motor Truck and L.C.L. Freight

BY F. J. SCARR,[1] NEW YORK, N. Y.

*The railroads are economically best suited for the wholesale movement of freight. The controlling factor in their operation is terminal capacity, and terminal costs and delays are the chief obstacles to their greater participation in the short-haul movement of less-than-carload traffic.*

*Under the present methods and conditions, the highway operator can move most less-than-carload freight for considerable distances cheaper than the railways. He will continue to maintain an economic advantage for the shorter terminal hauls, but a new instrument of freight transportation, the unit freight container, will permit the profitable rail handling of much of the traffic now trucked greater distances. This will necessarily result in the restoration of this traffic to the railways.*

*The container will use both the highway vehicle and the railroad in the portions of the total movement for which they are best fitted. The rail cost of less than one cent per ton-mile—or about one-seventh of the cost of movement by motor truck—will apply to the road-haul portion, and the terminal cost will be decreased because of the elimination of at least four man-handlings of the freight. The most important collateral benefits are:*

1. *Faster handling of freight from shipper to consignee*
2. *Relief of terminal congestion*
3. *Elimination of theft and damage claims*
4. *Reduction in packing and carting costs*
5. *Reduction in rolling stock devoted to L.C.L. service.*

TRANSPORTATION has advanced in economy and efficiency in proportion to the intelligent application of human ingenuity and capital investment. True advancement, however, is not in the development of any single phase to usurp in whole or in part the function to which any other phase is particularly adapted and better fitted to perform. A proper scheme of transportation demands that each means be employed in the task for which it is best suited.

President L. F. Loree of the Delaware & Hudson Company, in his address before the Holland Society last year, discussed the advancement of transportation in a unique manner. He measured such advancement by the increased productivity of the individual as outlined in the following quotation, which—with Mr. Loree's permission—has been briefed:

> The first transportation undertaken by man was a personal effort in which he packed his own burdens.....Under this method there may be transported daily 65 pounds 15 miles for each porter, or allowing 312 days for a year's work, 152 ton-miles.
>
> With the domestication of wild beasts, pack trains were organized....A horse of average force working for eight or ten hours per day might transport on his back 200 pounds at a rate of 25 miles per day over average level country. For a year of 312 days his performance would be 780 ton-miles.
>
> In the early eighteenth century.....highways were built with careful attention to grades and their surfaces properly metaled. Many cartage companies were organized and an allowance of one ton of goods for one horse was very general. With this power, 20 miles a day were covered, or for a year of 312 days, 6240 ton-miles....
>
> There were on the payrolls of the railroads of the United States at the end of 1925, 1,753,208 employees. Making a rather arbitrary division of these employees between freight and passenger service.... indicates that there were approximately 1,415,000 employees engaged in freight service. In the year 1925 the railroads transported 452,827,593,844 net tons one mile. Comparing the extremes only, we have 152 ton-miles per year as the paying load-carrying capacity of the porter. The railroads in 1925 transported 320,019 (paying load) per individual freight employee. That is, the productivity of the individual due to the achievements of management, as reflected in the concerted movement and in the ordered discipline; the use of capital reflected in the plant, the provision of power, and the multitudinous inventions and adaptations of machinery and tools; and his own intelligent industry, has been multiplied 2105 times.

For the purposes of this discussion, the productivity of the individual has been calculated when using the motor truck, the latest development of land transportation. These results, together with those previously discussed, have been listed in Table 1 for convenient comparison. This is offered not as conclusive as to accurate detail, but as indicative of general relations.

TABLE 1 PRODUCTIVE ABILITY OF THE INDIVIDUAL

| Means of transportation | Revenue freight per man per day | Miles transported | Ton-miles per year per man | Cost per ton-mile |
|---|---|---|---|---|
| Porter | 65 lb. | 15 | 152 | $10.250 |
| Pack horse (6) | 1200 lb. | 25 | 4,680 | 0.933 |
| Horse and cart | 1 ton | 20 | 6,240 | 0.380 |
| 2-horse dray | 2 tons | 20 | 12,480 | 0.240 |
| 5-ton truck | 5 tons | 100 | 156,000 | 0.065 |
| American railroads[1] | 3.06 tons | 309 | 295,000 | 0.009 |

[1] 1925 actual performance; other figures are potential.

While it is recognized that the figures in Table 1 are not accurately comparable, there are certain general and interesting conclusions apparent which are adequately supported and justified.

It is interesting to note the distinct periods into which this table divides transportation development. These periods are clearly marked in the two columns captioned "Ton-miles per year" and "Cost per ton-mile."

In the first period neither capital nor human ingenuity have been applied to an appreciable extent, with a minimum of individual ability and maximum cost as the result.

The second period finds the application of capital in the form of muscular power and the application of human ingenuity only to the extent of animal domestication. The result, however, is to increase individual productivity thirtyfold and reduce the cost by ninety per cent.

The third period is that of additional capital use and the first application of mechanical invention in the cart and dray. The result is again to increase productivity and reduce cost.

The final period seems to be the acme of development, as Mr. Loree points out in the last sentence quoted from his address. Herein the supreme application of human ingenuity, in the development of mechanical power as well as greatly advanced auxiliary means, is made possible by the unstinted and intelligent application of capital in the form of railways and motor vehicles. This has resulted in increased individual productivity and reduced costs to a seemingly extreme degree.

It seems that the final period has been reached. Advance from the present state will be the result, principally, of refinements of established principles and practices.

The general direction of such refinements is clearly indicated by the fundamental relations of our various means of transportation. Table 1 establishes in a general way the relative merits of the various forms of land transportation.

The railroad is supreme in its "mass transportation" ability. Economic law dictates its utilization to the greatest possible extent for the movement of that class of freight for which its equipment and facilities have been designed—in general, the movement of large volume for long distance.

[1] Scarr Transportation Service, Consulting Engineers. Assoc-Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The porter is supreme in his individual-package movement or retail transportation ability. His capacity, short radius of action, and high cost confine his field to the narrowest of limits.

Each means of transportation bears a definite relation to the others and to the general scheme in proportion to the traffic which its relative but varying limitations particularly fit it to handle.

### The Railroad and the Motor Truck

As this discussion is primarily one of the motor truck and a portion of the railroad scheme, it is necessary to examine the general relation of these two means more specifically. Therefore the data in Table 1 have been extended into further arbitrary divisions, as shown in Table 2.

TABLE 2 PRODUCTIVE ABILITY OF THE INDIVIDUAL

| Part | Means of transportation | Tons of revenue freight per man per day | Miles hauled | Ton-miles per man per year (312 days) | Cost per ton-mile |
|---|---|---|---|---|---|
| I | American railroads (All freight) | 3.06 | 309 | 295,000 | $0.009 |
| | American railroads (C.L. freight) | 3.43 | 309 | 330,700 | 0.008 |
| II | American railroads (L.C.L. freight) | 0.85 | 309 (?) | 82,900 | 0.032 |
| | 5-ton truck[1] | 5.00 | 100 | 156,000 | 0.065 |
| III | 5-ton truck (80 per cent load) | 8.00 | 33 | 82,400 | 0.090 |
| | 5-ton truck (40 per cent load) | 5.00 | 33 | 57,500 | 0.215 |
| | American railroads (L.C.L. freight) | ... | 33 | .... | 0.160 |
| IV | 5-ton truck (80 per cent load) | 16.00 | 10 | 55,900 | 0.115 |
| | 5-ton truck (40 per cent load) | 10.00 | 10 | 31,200 | 0.250 |
| | American railroads (L.C.L. freight) | ... | 10 | .... | 0.490 |

[1] Potential figures.

### Railroad to Handle Much of L.C.L. Traffic

Less-than-carload traffic constitutes approximately 4 per cent of the total railroad freight business and requires nearly 20 per cent of the rolling equipment for transportation. Table 2 (Parts 1 and 2) indicates that the handling of L.C.L. freight costs four times that of carload freight. This is due, primarily, to high (L.C.L.) terminal costs and low average tonnage per employee.

The potential performance of the motor truck exceeds the individual productivity of the L.C.L. freight employee. The greater cost per ton-mile, however, presents the complete usurpation of this business by the motor truck, and indicates that for much of this class of freight the railroad must remain supreme.

High railroad terminal costs, due principally to the high platform-handling expense, cause a material change in this relation for the shorter distances.

### Railroad Terminal Costs Favor Motor Truck for Short Distances

At 33 miles, the economic point below which the average railroad cost of handling L.C.L. traffic exceeds the revenue, the relation of the railroad and the motor truck is such as to favor the latter under good motor-trucking conditions and the former for average conditions.

At this distance, on the basis of cost alone, the railroad is superior to the 40-per-cent-load-factor motor truck,[2] while the 80-per-cent-load-factor vehicle[2] is capable of serving at less cost than the railroad and will also reduce the time element to the minimum.

It is assumed that ten miles is the outside radius of the daily ability of the horse-drawn vehicle. This distance is well within the reach of the motor truck, which vehicle seems destined to play a middle role between the horse-drawn vehicle on the individual or retail side and the railroad on the mass or wholesale side. Dependable statistics indicated that, of the large and ever-increasing amount of traffic being handled over the highways, nearly 50 per cent is moved less than ten miles. At this distance, as indicated in Part IV of Table 2, the motor truck is eminently supreme, both in cost and expedition of movement.

[2] These percentage load factors are approximations of the average attainments of organized motor transport for "one-way" and "two-way" loads.

### Present Conditions at Variance With Economic Law

While economic law is certain to prevail, it is not as prompt of action as it is correct of judgment. Human effort to influence the functioning of this law is slow of adjustment to meet new developments. The cost of operation, while indicating the economic relation, is not a correct measure of the conditions which influence the flow of today's freight traffic. The cost to the shipper, involving arbitrarily fixed rates, and to a material extent the expedition of completing the through movement from door to door, are the chief factors affecting a choice of mode. These factors, considered in their true light, together with other related factors, present a vastly different picture of the present relation of rail and highway transportation.

### Shippers Interested in Complete Movement

No transportation is of value except as a part of the completed movement from point of origin to point of destination. That the shipper is also interested in the element of in-transit time is evidenced by changed business conditions and demands. The through movement and minimum costs, however, remain the shipper's prime interest.

In the movement of L.C.L. freight traffic the railroad performs, in general, but one portion of the completed movement. Some form of highway transportation accomplishes the collection and distribution. This condition is also true of a considerable portion of carload merchandise traffic.

The shipper is also burdened with the necessity of crating merchandise. That this item is of greater expense and weight when railroad movement is contemplated than when only highway transportation is involved, is well known.

### Through Movement

The through movement from origin to destination involves, generally, three and four elements of expense when moved respectively by highway alone or by highway and rail. These factors are: Crating, Carting, Freight on Net, and Freight on Tare. These factors in combination determine the true relation of rail and highway transportation as dictated by today's conditions. Properly evaluating these elements of the completed movement indicates that the motor vehicle can successfully (and actual operations demonstrate) compete with the railroad handling of L.C.L. traffic for considerably greater distances than the accurate measure of economic law seems to dictate.

Today's conditions are not in accord with economic law. In spite of the human tendency to resist any change in the established order, the shortcomings of the present system will be overcome and the advantages offered by new measures will be pursued.

The motor vehicle is burdened with little terminal expense. The railroad, particularly in L.C.L. traffic, is tremendously taxed by high terminal costs—made up largely of handling expense. These characteristics are clearly demonstrated in the flat motor-vehicle and abruptly ascending L.C.L. cost curves for the shorter distances.

1 High railroad-terminal L.C.L. expense must be reduced
2 High motor-vehicle line-haul expense must be avoided.

### Coordination of Effort

These principal expense factors of the two modes of transportation under consideration can be bettered materially by mutually coordinated effort. In the matter of terminal expense the motor vehicle is reasonably free, that item being largely absorbed by the merchant, while the railroad pays from $0.16 per net ton-mile (at 33 miles) to infinity, depending inversely upon the distance. In line-haul expense the motor vehicle is penalized a fairly constant sum of $0.065 per net ton-mile, while the railroad does not exceed $0.032.

Two conclusions result directly from the foregoing discussion:

1 To permit the utilization of railway transportation in the line haul and highway transportation in the terminal movement to the greatest possible extent demands that some efficient, economical, and rapid means of transfer from one medium to another be devised and placed in service.

2 To permit the application of a plan of mutual coordination between rail and highway transportation requires that present rate structures be revised to be as fully as possible in accord with the relative cost of operation of each mode.

### The Unit Container

Accepting these seemingly academic but exceedingly real and practical conclusions as correct, the manner of making them effective is immediately of interest. The refinements that are necessary in advancing from our present state are simple and of proved practicability. The unit-container method of handling L.C.L. traffic will go far in the accomplishment of the above purposes.

It is not proposed to discuss here the advantages or probable method of applying the unit container to our transportation requirements. For an able discussion of this new and important phase of transportation, reference is made to a recent paper entitled, "The General Theory of Container Use," prepared by Bernard Allen, one of the author's consulting-engineering associates. Mr. Allen has also taken up the subject in a recent issue of the *Railway Age*. Here is a railroad man of many years' experience with the Canadian National Railways looking forward to the general and widespread acceptance of this specialized method of handling L.C.L. freight traffic. The unit container is not new, nor is its application to a coordinated plan of rail and highway transportation new. Such plans have been advocated and to some extent successfully utilized for a great many years; the first patents being granted on such devices in England in 1845.

The conditions, however, which make its general and widespread use certain within the near future are of reasonably recent development. The motor vehicle, with its flexibility, has not only made container interchange possible and from an economic standpoint desirable, but has brought on a demand for the type of service that its adoption will augment. The high cost of platform labor has forced the adoption of all possible labor-saving devices to keep the costs within the regulated revenue.

New business demands for lower inventories and more frequent shipment of smaller quantities with consequent shortened warehouse clearings have created conditions particularly appropriate to usher in this new development.

As other special classes of traffic have been served by special equipment and facilities, so L.C.L. traffic—the most expensive division of the railroad business—will gradually be accorded the same treatment, with correspondingly favorable results in increased efficiency and economy. The present stage of transportation development will by this means have advanced through additional refinement, with advantage to individual productivity, cost, and the shipping public.

## Discussion

K. J. Ammerman.[3] The setting up of the motor truck as a competitor of the railroads has been the result of a number of factors the importance of which has kept pace with the increase in population and the ever-increasing congestion in and around the large cities.

Years back, when this congestion was not as marked as it now is, the railroads were able to carry from place to place in a reasonable length of time the commodities and types of freight which have to a certain extent been lost to them. Perishable farm products and rush freight in small lots which have to be carried a relatively short distance, say, 75 to 100 miles, are referred to particularly in this connection. With the increase in traffic of all kinds the congestion in railroad terminals has become so great that the length of time required to move freight from the outskirts of the city into the freight terminal represents about two-thirds of the total time required to haul the commodity from its source to the terminal. Under such conditions it was found that a motor truck could carry such freight in one-half the time required by the railroad.

To increase the size of terminals so that the congestion would be comparable with that which existed years ago would be too costly. It seems to the writer that a further recognition of the motor truck as an ally rather than as an enemy of the railroad would achieve the desired result of returning a large percentage of the lost freight, by reducing the shipping time through the establishment of freight terminals on the edge of the congested area and delivering freight direct to the consignee from that point. By so doing, the time from consignor to consignee would be cut to a point no overland trucking company could approach.

The comparison of truck speed and railroad speed is all in favor of the railroad until the congested area is reached. From that point to the consignee the time would be the same either by a local truck or overland truck, less the time of transferring the freight from railroad to truck.

The margin of time in favor of the railroad on the major portion of the haul would more than cover the transfer time. This margin of speed, however, is rapidly being reduced through the very noticeable tendency toward heavy trucks capable of speeds formerly thought possible only in light trucks.

The above-mentioned method would not militate against the trucking interests, as local trucking would be more profitable than the overland haul, provided the railroads and trucking interests cooperated in adjusting rates to their mutual satisfaction and still did not increase the rate to the shipper.

W. C. Sanders.[4] The paper is very interesting, especially that part which deals with the cost of L.C.L. freight by steam road and by motor truck. The limiting factors of each are very clearly brought out.

The motor truck undoubtedly has a definite place in the transportation system of the country as an adjunct or supplement to the steam roads, holding a position similar to the bus, and it affects steam passenger service.

The writer believes that L.C.L. freight containers with night pick-up service, using either gas-electric or oil-electric motive power, will greatly reduce the cost of L.C.L. short-haul freight.

The advantages of the container-car system are as follows:

1 It will furnish a means of expediting delivery of less-than-carload lots of commodities by eliminating the time and expense of rehandling, checking, and trucking.

2 The immediate unloading and loading of containers promptly

[3] American Car and Foundry Motors Co., New York, N. Y.

[4] General Manager Railway Division, Timken Roller Bearing Co., Canton, Ohio. Mem. A.S.M.E.

releases rolling stock, clearing the yards of cars and reducing congestion.

3 It will tend to keep the car moving at all times, making possible double the mileage now made by an ordinary piece of rolling stock in L.C.L. freight service.

4 It will allow a considerable reduction in terminal costs.

W. E. Symons.[5] With respect to the use of the motor truck and bus and their relation to the railway industry, there are a number of points of interest, some of which are somewhat clouded by a rather unfair view of the situation. To illustrate conditions, let us paint a picture of a typical American city and its surrounding territory, with railways radiating in all directions. Imagine an industry out in one direction making container boxes, let us say, which are required by another industry off in another direction. Assume these towns to be 15 miles from the city. The usual method of procedure is to order from the manufacturer of the container a carload lot either by telephone, telegraph, or letter. This is then transmitted to the railway operating office; it goes to the trainmaster, then to the yardmaster. A box car is selected for the shipment; it is taken over and delivered to another railway; then it is hauled out to where it is to be used, and finally loaded. It may be the shipment goes out on this line. Two, three, or even seven days may pass before those containers are delivered.

With the use of the motor truck the order is simply telephoned to the container manufacturer. A truck is backed up to the factory and in two or three hours the order is carried across to the buyer and the shipment awaiting the containers is on its way inside of 24 hours.

If a manufactured article is of a character requiring extra-heavy packing or casing for foreign shipment or for great distances, and lighter for local deliveries, in truck shipment the character of the container is much simpler, and its cost, which is always passed on to the consumer, is much reduced. Sometimes it is possible to dispense with it entirely. The railways have been somewhat backward in urging the use of trucks for this work, and in cooperating with the companies that provide trucks.

Another interesting and important feature is the passenger business. About a year ago a member of the passenger department of a certain railway at a meeting solicited the aid of the other passenger representatives in securing some protection against the inroads of the motor bus. He cited the fact that his company had lost a million dollars in passenger business the year before. He was very much disturbed about it. However, he failed to note an increase of freight earnings of about $40,000,000, a great deal of which was due to the fact that salesmen, using automobiles or motor buses, had driven through the country instead of relying upon local passenger trains of uncertain schedule. They were then able to visit six, eight, and sometimes ten towns per day, and consequently increased the freight shipments over that road several carloads. Such records when properly analyzed not only speak well for the use of the motor truck, automobile, and motor bus, but show that they are a help to the railways rather than a detriment.

There is one other feature, however, on which the railways have a just complaint, it seems to the writer. It is this: Taxes of the railways have crept up from about $100,000,000 to $400,000,000 per year. A great deal of this money has been used in building highways on which competitors of railroads may haul freight and passengers; in other words, the railways have been forced to aid in building a superstructure on which their competitors may do business. That is not fair, and there should be some readjustment to relieve the situation.

[5] Associate Editor, Engineering Publications, Angus Sinclair Publishing Co., New York, N. Y. Mem. A.S.M.E.

One more feature: Every one who has to do with shipping knows that there is a great deal of trouble in getting claims for damages or loss adjusted. It is not that the railways want to be unfair, but because the evidence or facts are frequently difficult to obtain, and sometimes it is very confusing because the articles pass through so many hands. But in the case of an immediate delivery by motor truck, the man who receives the articles and makes the deliveries is usually authorized to give a slip for damage or for loss of an article, and therefore the adjustment can be made immediately and be made accurately and satisfactorily to both parties concerned. There is an excellent field to be developed in this direction.

N. D. Ballantine.[6] The writer can certainly concur in the idea that there is a real field for motor vehicles in coordination with railway service in this country. It may be of interest to know that in six years, from 1920 to 1926, there has been a decrease of more than 25 per cent in less-than-carload traffic carried by class 1 railroads. Now that is not a measure of actual loss to the railroads because they actually had about 50 per cent more cars of less-than-carload freight. That works out in this way: If a given amount of merchandise is moving between two points, the railroad has to provide a certain number of L.C.L. or "way-freight" cars as we term them. Let us assume that it has to run one car which is capable of handling practically ten tons of merchandise, but an independent trucking concern hauls five tons of it. The railroad's cost of service in moving the ten tons is so small over the cost of handling five tons that it is rather difficult to determine what it amounts to, because the terminal charge is already practically taken care of in both cases. Hence there is a loss of revenue from 5 tons and no appreciable reduction in expense.

From this it is evident that the 25 per cent reduction in less-than-carload freight revenue referred to above does not in any wise measure the actual loss to the carriers. The same principle applies with respect to a lot of their passenger traffic.

The use of the container involves a more difficult problem and it is analogous to that of the mariner; it is not the "average depth" he wants to know—if he hits the high spot he is out of business. It is specific problems that have to be analyzed in the case of a container. If one uses a flat car, for example, he has this problem: About 60 per cent of all the carload traffic is east- or north-bound, and about 40 per cent moves in the other directions. The percentage in loaded box cars, which carry the L.C.L. freight, is probably greater than that, although the exact figures are not at hand, and probably are not available. There is a predominant and excessive west-bound movement of empty box cars throughout the entire United States. The protection of merchandise in a west-bound car that otherwise would move empty is not such a serious problem if it is put in one or two cars.

Let us assume that empty box cars are moving into a grain territory and that a shipper has merchandise to move from a jobbing point to the grain territory. Suppose ten tons are loaded into one car and that there is an empty car to move to the same point. It is better to use two cars and put five tons in each car, distributing one here and one there, and thus save time by relieving the crew of handling five tons. In other words, a certain amount of intermediate train expense is eliminated.

The tonnage per car for a carrier of less-than-carload freight is not an indication in any way of the efficiency with which the cars are utilized, because oftentimes a reduction in the number of tons per car on west-bound merchandise box-car loading is a very much more efficient procedure than the other method.

# High Steam Pressure and Condensing Exhaust for Locomotives

## A Discussion of Present Progress—Cycle Efficiencies—Auxiliary Requirements—Machine Efficiencies—Transmission Efficiencies—Thermal Efficiencies—Value of Locomotives—Possible Turbine Arrangements

By JAMES M. TAGGART,[1] NEW YORK, N. Y.

INCREASING steam pressures for power production always has for its primary objective an economy increase. For different Industries the economic return will be the result of different factors. Thus with industries requiring high-pressure steam for their processes an advance in generating pressure often will provide for power generation above the process pressures. In this case a decrease in first cost due to the smaller boiler plant required normally will be joined to a large reduced fuel or power cost to increase the economy. In central power-station practice the only increase in economy to be expected at present is a decrease in fuel charged per unit produced. Normally this saving must be balanced against an increased fixed charge to ascertain the resulting economy. There is also present in the case of central stations and most industrial plants the question of special design that may, if not successful, increase the maintenance costs.

For railroads higher steam pressures promise an increase in capacity as well as a decrease in fuel requirements. As will be pointed out later, the increase in power capacity will be approximately in a direct ratio with the increase in thermal economy. Since fuel cost is only about 25 to 35 per cent of the cost of locomotive operation, it follows that the capacity increase to be anticipated is three to four times as important.

With railroads also numerous like units are normally built at the same time. Accordingly, the uncertainties and high cost of special design can be largely avoided by preliminary trial tests.

It is thus evident that investigations to determine the optimum pressure of steam generation for central stations or other industries do not apply in considering steam-driven locomotives.

### Present Progress

In Europe where fuel conservation is relatively more important than in the United States, two designs of super-pressure locomotives have been built. One of these, namely, the Schmidt-Henschel locomotive, has in addition to the super-pressure section a lower pressure of steam generation. The drive for this locomotive approximates the standard. The other super-pressure locomotive, namely, the one built by the Swiss Locomotive Works, generates all the steam at 850 lb. per sq. in. and uses a high-speed, triple-expansion engine with a gear transmission for driving. These super-pressure locomotives are non-condensing. Condensing effect has, however, been applied to several types of turbine-driven locomotives that have been tried out in Europe. The trials have shown an improved thermal economy. In addition to the super-pressure locomotives and the condensing locomotives a number of locomotives in Germany have been equipped with the uniflow type of cylinder.

### Limits

Apparently these different developments have to some extent a common bearing. Thus, condensing effect with its promise of a cleaner feedwater is especially important with super steam-pressure generation, while any form of drive that will more economically utilize steam expansion has an enhanced valuation when the range of pressure is increased.

With this in view the estimates and computations in this paper are based on equipment including condensing effect and consideration of both turbines and uniflow-cylinder drives. In order to confine the treatment within reasonable limits, general arrangements and types of designs have been taken as a basis for the theoretical treatment. These are listed below and are more fully described in the September and October, 1927, issues of the *Railway Mechanical Engineer*. In no case is there an extension of effects beyond a possible economical practice.

Boilers—water-tube, preferably non-water-line, constant-temperature type

Economizers and superheaters—to form a part of the boilers

Furnaces equipped for pulverized- or liquid-fuel burning

Air preheaters

Forced- and induced-draft fans

Auxiliaries—motor driven in most cases

Feedwater heating

Condenser—probably of the air-evaporative-cooled type

Main drive arrangement—either

1. Turbine with gear transmission
2. Turbo-generator-motor drive
3. Engine, uniflow, multiple expansion direct
4. High-pressure engine direct and low-pressure turbo-generator motor.

For arrangements Nos. 3 and 4, see Figs. 19, 20, and 21.

### Assumptions

Calculations involving steam at the higher pressures are subject as yet to some uncertainty. It is a field where the authorities and most of the tests made vary. The variance is, however, not enough materially to affect the results. For this paper the enlarged steam tables of Prof. H. L. Callendar have been used.

Assumptions of conditions of operation are limited by numerous factors. Thus in the equipment listed the boiler is mentioned as one of constant temperature. With the non-water-line boiler the control would be adjusted to produce the desired temperature, and with a reliable control a higher temperature could be carried than where dependence was placed on calculated heat transmissions. Thus in the latter case greater leeway would need to be allowed for unusual fire conditions. A figure of 700 deg. fahr. has been taken as a conservative initial steam temperature now in use. With this temperature as a normal maximum and with good design all parts can be made up from standard materials. It seems probable that in the near future 800 deg. fahr. may be safely used with special high-temperature steels. Accordingly values have been given also in most cases for 800 deg. initial temperature.

Volume requirements and atmospheric temperatures limit the economical vacuum. An absolute pressure of 2 lb. has been assumed for the condenser pressure. This assumption is

[1] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.

Presented at a meeting of the Metropolitan Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, November 15, 1927.

based on an estimate of performance at 70 deg. fahr. atmospheric temperature. A further cooling effect of the liquid down to 100 deg. fahr. is assumed in determining efficiencies. Thus 100 deg. fahr. is considered as the temperature of the boiler-feed pump suction, whether taken partly from the condenser or all from the supply tank into which the condensate is discharged. In practice the vacuum would vary with the load as well as with the air temperature and flow.

The size of the locomotive power plant as well as the space requirements limit the economic value of complicating the equipment to reduce fuel consumption. Some arrangement of feedwater heating is apparently necessary for good results at high pressures. The type and design of the drive and heaters provided would determine largely the number in series that could be advantageously used. The best location of the heater or heaters relative to their operating pressures also depends to some extent on the form of drive. Normally two heaters, of the closed type, in series have been assumed. With the heater efficiencies probably attainable, a third effect would hardly seem justified. A better heater efficiency such as is obtainable with open heaters or special conditions might change this conclusion. Curves of cyclic efficiency (Fig. 5) are also given for a single closed-heater and a double open-heater cycle. These are for comparison only. All thermal efficiencies unless otherwise noted are based on the use of two closed heaters in series. These heaters are assumed as draining and venting into the steam space of the heater of next lower pressure, and into the condenser from the lowest-pressure heater.

Values are given for one 100-deg. fahr. reheat effect in addition to the regenerative effects. It is probable that usually the installation of reheat equipment will not be economical. Arrangement No. 4 appears, however, to be a possible exception. Furthermore it seems possible that in the near future a mercury-vapor reheater may be developed that may change the situation.

## Cycles

Referring to combinations of steam flow as cycles is convenient and in accordance with recent practice, though it is extending the meaning of the word "cycle." Thus bleeding a prime mover at different pressures to successively raise the temperature of feedwater comprises in fact a number of separate cycles, and in the author's experience was formerly called "series heating." It is here for convenience referred to, as suggested in the paper of Messrs. Hershfeld and Ellenwood published in the 1923 Transactions of the A.S.M.E., as the "regenerative cycle," and is indicated below and on the figures as the S-cycle for brevity. Where reheat is added the cycle is referred to as the SR-cycle. Figs. 5 and 6 show straight Rankine-cycle efficiencies for comparison. They are marked A-cycles.

The advantages of the regenerative cycle are well known and have been covered recently in numerous articles as applied to high

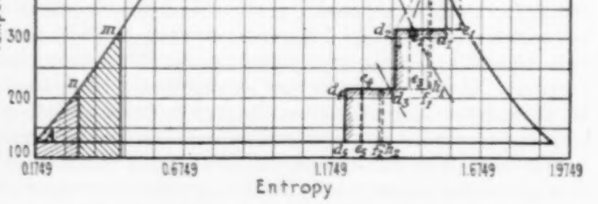

Fig. 1 Temperature-Entropy Diagram, 800 to 700 Deg. Fahr., S- and SR-Cycles

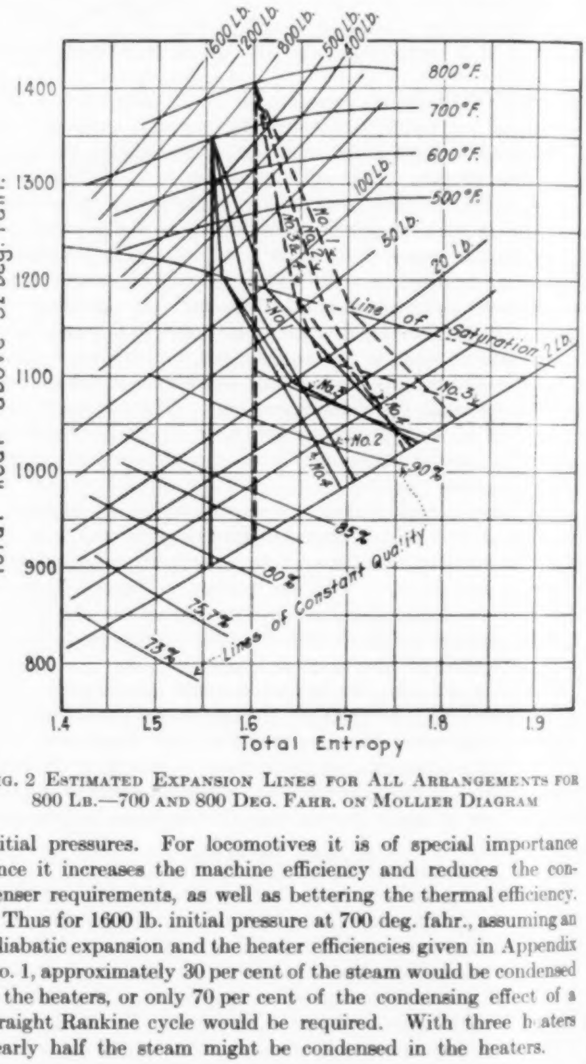

Fig. 2 Estimated Expansion Lines for All Arrangements for 800 Lb.—700 and 800 Deg. Fahr. on Mollier Diagram

initial pressures. For locomotives it is of special importance since it increases the machine efficiency and reduces the condenser requirements, as well as bettering the thermal efficiency.

Thus for 1600 lb. initial pressure at 700 deg. fahr., assuming an adiabatic expansion and the heater efficiencies given in Appendix No. 1, approximately 30 per cent of the steam would be condensed in the heaters, or only 70 per cent of the condensing effect of a straight Rankine cycle would be required. With three heaters nearly half the steam might be condensed in the heaters.

## Heat-Entropy and Temperature-Entropy Diagrams

In Figs. 1 and 2 the temperature-entropy and heat-entropy (or Mollier) diagrams are shown for 800 lb. pressure and 700 deg. fahr. and 800 deg. initial temperatures. Fig. 1 also shows a 100-deg. fahr. reheat effect. Fig. 1 gives a proportional value for the cycle, since when steam is withdrawn to the heaters the curve ceases to indicate the true state of the steam. By relocating the saturation curve an idea of the action can be approximated. On Fig. 2 no steam withdrawal has been indicated nor reheat effect shown. In addition to the adiabatic, other expansion lines have been drawn to show the estimated results for the different arrangements of driving. These lines are of course merely indicative. It should be kept in mind that with the regenerative effects considered, only the steam going to the condenser would follow the complete expansion shown. Other

portions of the steam would be drawn off at various points of the expansion to be condensed in the heaters. It should be noted that during the higher pressure and temperature range the expansion indicates a better efficiency. This for turbines is due mainly to the smaller moisture content and for cylinder expansions to the reduced exhaust and throttling loss. Thus all steam

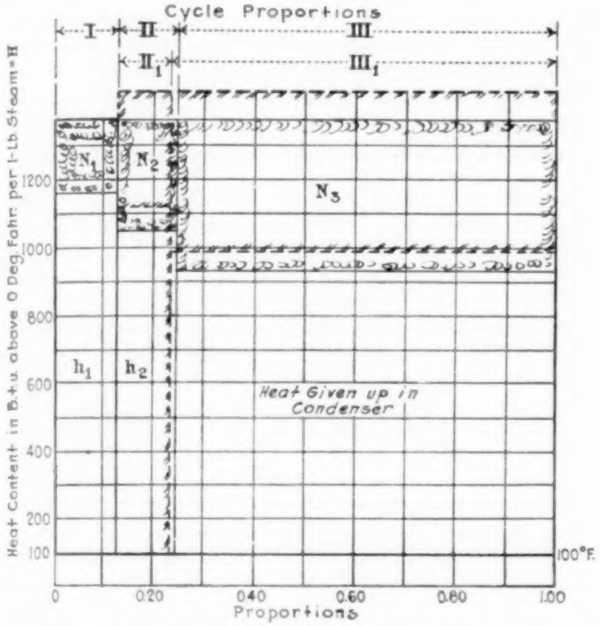

FIG. 3 COMPARATIVE HEAT DISTRIBUTION. FULL LINES—S-CYCLE, 800 LB., 700 DEG. FAHR., AND TWO HEATERS. DOTTED LINES —SR-CYCLE, 800 LB., 700 DEG. FAHR., AND TWO HEATERS

that is condensed in the heaters can be more efficiently used than that going to the condenser.

The expansion lines on the Mollier diagram are often spoken of as the characteristic lines for a steam-driven machine. They do not show the efficiency since they do not give the proportions between radiation, leakage, and friction losses. However, they indicate the efficiency when leakage is low, since radiation for any machine can be estimated closely.

In the diagrams shown the action of the steam has been taken as a whole. It can more simply and correctly be considered as divided up into several parallel cycles. Thus the steam expanding to each heater or the condenser pressure would form individual Rankine cycles simple to consider. Fig. 3 represents the heat and power effects of a group of parallel cycles. It is simply a block area with the ordinates indicating the total heat per unit quantity of steam and with the abscissas showing the proportional amounts. It might be called a heat-distribution diagram. Thus the ordinates are marked off in B.t.u. per pound of steam and the abscissas in percentages. I shows the relative per cent of steam condensed in heater No. 1, II that condensed in heater No. 2, and finally III the proportion that goes to the condenser.

$N$ is used to indicate the heat drop and $h$ the heat in the exhaust to the heaters. The base line is taken at 100 B.t.u., or the approximate heat content per pound of the cooled condenser condensate above 0 deg. fahr. The total $N$ areas divided by the total $H$ above the base line less the $h$ area would give perfect efficiency for the conditions assumed. An approach to actual efficiencies can be obtained from this plot. Thus by deducting from the $N$ areas the losses due to radiation, leakage, and friction, and from the $h$ areas the losses due to heater radiation and ventage, and transferring the drainage loss from $h_1$ to $h_2$ and from $h_2$ to the condenser loss, the actual efficiencies will be approximated. This approximation will not allow for leakage and friction losses from $N_1$ and $N_2$ being utilized in $h_1$ and $h_2$, respectively, and acting to change the proportions I, II, and III.

The plot of Fig. 4 was prepared to bring out more clearly the variance in condenser effect with increased pressure and regenerative effect. Thus the dotted lines show the area for 400 lb. pressure and 700 deg. superheat with a single heater. The full lines indicate the values for 1600 lb. and 700 deg. with three heaters in series. With engine drive, added heating effects may sometimes be advantageous to reduce the exhaust volume to the condenser.

### CYCLE EFFICIENCIES

The term "cycle efficiency" is taken to apply to the ratio between the total adiabatic heat drops and the net heat given to the steam by the boiler. Thus these efficiencies include allowance for heater efficiencies. The methods of figuring these efficiencies and the figures they are based on are given in Appendix No. 1. The curves of Figs. 5 and 6 show the results obtained for the different initial temperatures and cycles with the pressure varying between 400 and 1600 lb. In all cases a rapid increase in efficiency is indicated up to approximately 800 lb. pressure, and a smaller rate of increase above.

Relatively small changes in heater locations as well as heater efficiencies will change the cyclic efficiencies. The locations assumed are approximately correct for the best efficiency, but are based partly with the idea of securing the best heating effect for the minimum heating surface. The location of the reheat effect has been taken as coincident with the highest-pressure bleeding point.

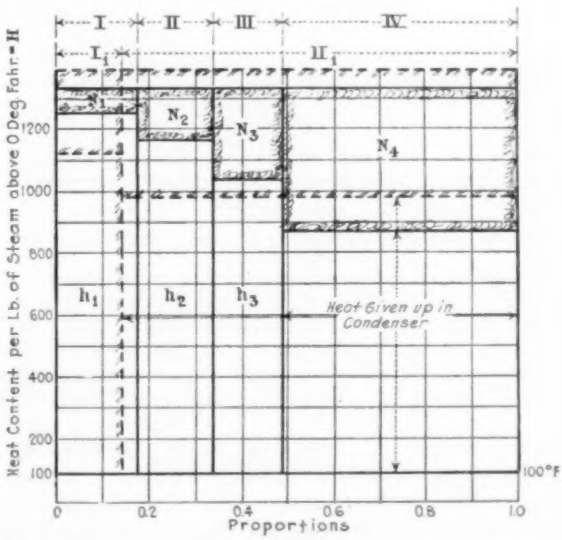

FIG. 4 COMPARISON OF HEAT EFFECTS. FULL LINES—S-CYCLE, 1600 LB., 700 DEG. FAHR., 3 HEATERS. DOTTED LINES—S-CYCLE, 400 LB., 700 DEG. FAHR., ONE HEATER

### AUXILIARY REQUIREMENTS

From these cyclic efficiencies the net thermal efficiencies for all the arrangements are computed. The first step consists of allowing for the auxiliary requirements. Fig. 7 gives the auxiliary requirements for each pound of steam generated. The requirements are given in B.t.u. and represent the power calculated as required at the shaft of the fan, pump, etc., as the case may be. The efficiencies assumed and the methods of

computing are given in Appendix No. 2. All requirements were found to vary about directly with the pressure, or as a straight line. The only auxiliary that shows an increased power for increasing pressures is the boiler-feed pump. The increase in power for this item counterbalances all other decreases so as to produce a large total increase. Draft requirements and

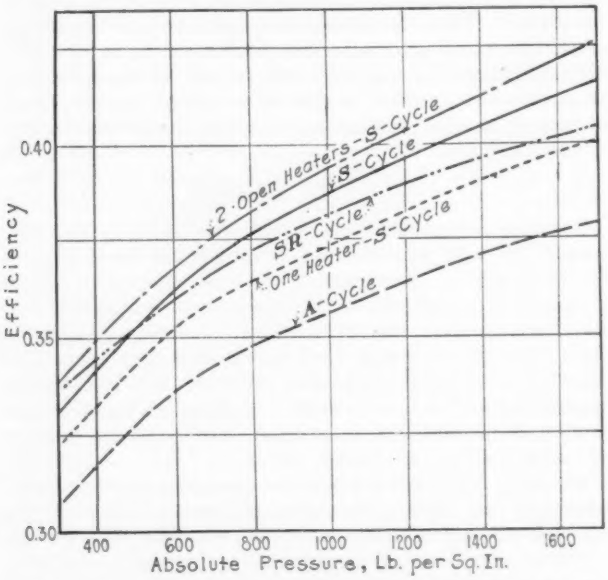

FIG. 5 COMPARISON OF CYCLE EFFICIENCIES, 700 DEG. FAHR. INITIAL STEAM TEMPERATURE

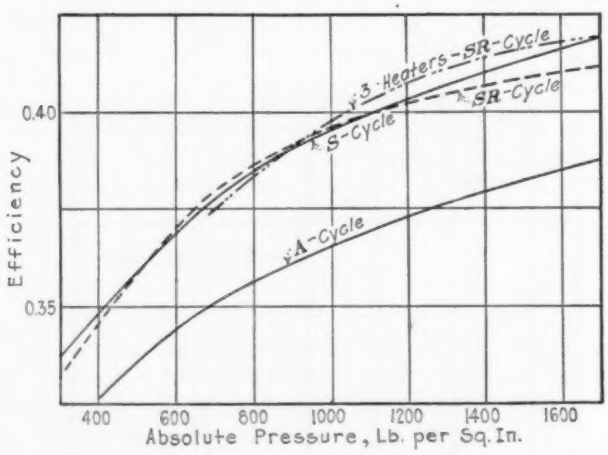

FIG. 6 COMPARISON OF CYCLE EFFICIENCIES, 800 DEG. FAHR. INITIAL STEAM TEMPERATURE

condenser-auxiliary requirements would vary normally with the cycle as well as with the pressure. To avoid too much complication an average for the various cycle requirements was assumed for each pressure. A total draft head of six inches of water was assumed for average loading with the type of boiler and furnace considered. For the condenser the principal power requirement would be for air blast. With the design suggested the train motion would partly furnish the head at high speeds. The fan was, however, considered as supplying the total air flow.

With the first and third arrangements a separate turbo-generator is proposed to furnish power for the motor-driven auxiliaries, and its machine and transmission efficiencies are shown in Figs. 8 and 10. With arrangements 2 and 4 the transmission efficiency is taken the same as for a separate turbo-generator, and the machine efficiency the same as for the main drive. It is probable that the induced-draft fan and condenser air pump might need to be steam-actuated. For convenience they have been considered as motor-driven. Where steam is used the net efficiency might even be higher if the steam were bled off at some intermediate pressure.

Total B.t.u. requirements were thus found for the different arrangements and cycles, and were taken from the adiabatic heat drops to obtain modified cyclic efficiencies for each arrangement. From these values the net thermal efficiencies were obtained by including the boiler, transmission, and machine efficiencies for each arrangement.

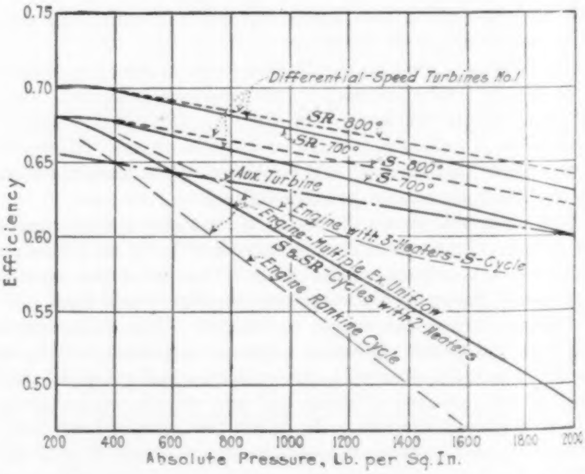

FIG. 8 MACHINE EFFICIENCIES FOR ARRANGEMENTS 1 AND 3 AND AUXILIARY TURBINE

## MACHINE EFFICIENCIES

The term "machine efficiency" is taken here to indicate the ratio between the adiabatic heat drop for any steam expansion and the power delivered by the steam-driven unit. The power delivered is taken at the shaft for turbines and at the axle or driving wheels for engine drive. In the latter case only the friction of the crankshaft bearings should be included.

Figs. 8 and 9 show the machine efficiencies estimated for the different arrangements, pressures, and cycles. These efficiencies are indicated as varying in a straight line with the pressure.

What efficiencies can actually be realized will depend somewhat on the designs that may be evolved. These designs always will be compromises in which efficiency will be sacrificed to some extent. It s believed that the values set down are conservative. The efficiencies are intended to represent what may be attained for average loading, or between one-half and three-fourths of full load. At the lower pressures the values were taken from guarantees and tests on units approximating the power requirements, and deductions were made to allow for the limitations probable, due to the special service. With turbines, loading below ratings means normally operating at a reduced throttle pressure unless by-pass governors are depended on to attain rating. In this latter case maximum efficiency would occur somewhere below rating.

The slopes of the turbine-efficiency lines for the higher pressures are not as steep as have been given in other published articles for the Rankine cycle. This is due to two modifications introduced. Thus, as pointed out previously and as shown in Fig. 4, when the pressure increases, with the cycles used here, a greater portion of the steam is condensed in the heaters or in the range of higher efficiency. Thus the influence of moisture in reducing total efficiency is lessened. This in itself should about account for the difference. In addition, it is assumed that a considerable proportion of the moisture may be drained off to the heaters with the bled steam. This assumption is based on the observation that the moisture accumulates near the periphery of the turbine as soon as condensation commences, due of course to centrifugal force. Since the values for machine efficiency do not include heater efficiencies, except for the drop in pressure in the steam flow, all efficiencies would be combination Rankine effects.

Higher initial superheat and reheat are considered as increasing the attainable turbine efficiency, due of course to reducing the moisture content. The differential would, however be reduced somewhat since additional superheat and reheat would also reduce the heater condensation with the heater locations assumed.

With arrangement No. 1 lower efficiencies were taken than for a constant-speed machine, since an average load would naturally occur at a reduced or less efficient speed. It is probable that for freight service where the highest loads are often at low speed the efficiencies set down may be high for average loading. It is also probable that smaller units would normally be used for No. 1. Thus for large locomotives at least two separate drives would be required to distribute the driving stresses.

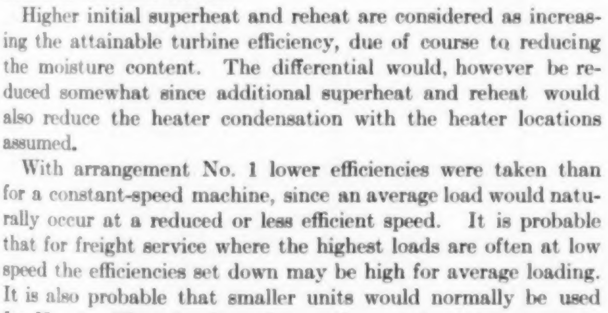

Fig. 9 Machine Efficiencies for Arrangements 2 and 4

Arrangement No. 2 is assumed as one constant-speed turbine driving a direct-current generator through gears. Thus the turbine could be made as best suited for efficiency, aside from the space limitations.

At present, engine-driven locomotives have a machine efficiency of approximately 72 per cent for simple engines at 200 lb. pressure, 550 deg. fahr. temperature, and approximately 20 lb. exhaust pressure. Compound engines operating on 300 to 350 lb. and 650 deg. fahr. show about 70 to 71 per cent machine efficiency. These figures are a little uncertain as nearly all locomotive tests lump the steam consumption for auxiliaries with that used for the main drive. Superheat has no effect on engine machine efficiency as here expressed since moisture does not lessen it. The main loss would be, with engine drive, the restricted expansion and throttling exhaust at the low exhaust pressures assumed here. This loss would be reduced considerably by the use of the uniflow-exhaust principle. In fact, simple uniflow engines show about the same machine efficiency with

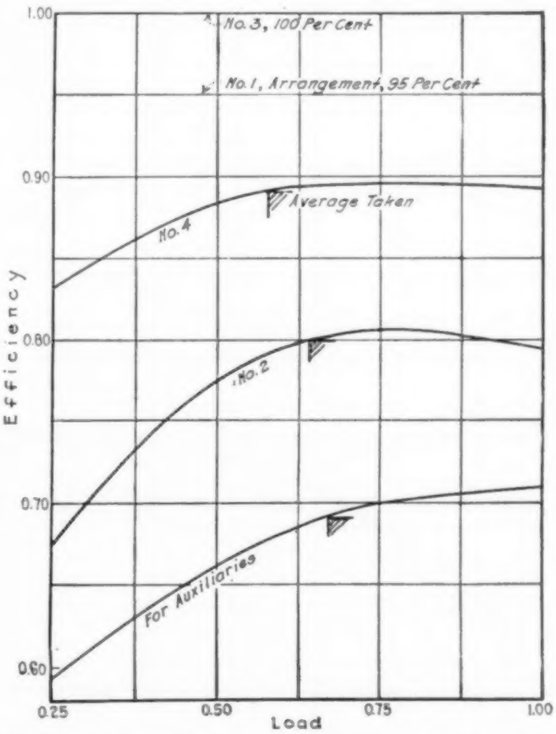

Fig. 10 Transmission Efficiencies for the Different Arrangements

2 lb. back pressures for 200 lb. as standard simple engines for 20 lb. This is due to reduced cylinder condensation, reduced clearance, and a reduction in the exhaust throttling loss. Any uniflow cylinders used for locomotives would have to be modified to take care of excessive compression and to give a suitable starting acceleration.

As the pressure is increased the relative total expansion-rate increase is not entirely in proportion to the steam-volume change due to the increased condensation. It further will be reduced with the cycles here considered by the heater condensation. Thus at 1600 lb. pressure and 700 deg. fahr. nearly 30 per cent of the steam will be condensed in the heaters or will operate at a fairly high machine efficiency. This point is clearly brought out in Fig. 8 where the machine efficiency for a Rankine cycle and a three-heater cycle are shown in addition to the curve for the two-heater-engine arrangement. In addition, the decreasing initial volume of the steam with the increase in pressures will permit the design of cylinders to be partially proportioned to suit the increased expansions. All these features were considered carefully in determining the machine efficiencies shown. The slope of the curve for engine drive shown in Fig. 8 probably could be bettered with a careful design.

Thus while the initial value of 69 per cent for 200 lb. is high for a Rankine cycle and present equipment used condensing, it proves out as conservative with a regenerative cycle and a uniflow drive suited for economy.

In arrangement No. 4 the machine efficiency would be a com-

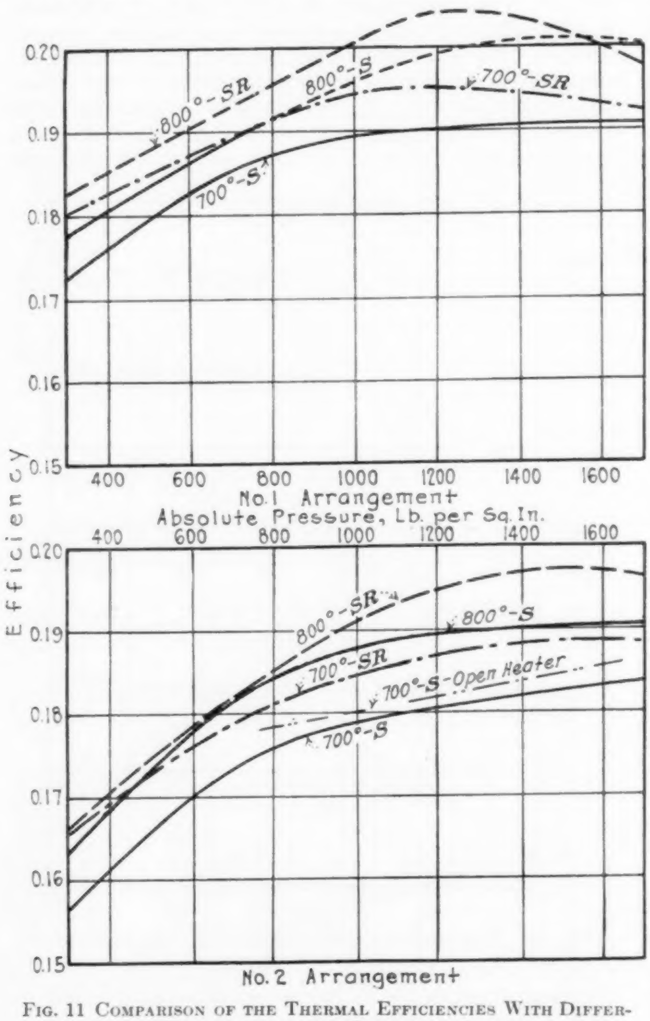

Fig. 11 Comparison of the Thermal Efficiencies With Different Initial Temperatures and Cycles for Arrangements Nos. 1 and 2

bination of engine efficiency at the high pressures and turbine efficiency at the lower pressures. The engine efficiency is not considered as changing for the different cycles or superheats. The low-pressure turbine is considered as increasing in efficiency with reheat but as not varied for the initial superheat, since with either 700 or 800 deg. initial temperature and without superheat this turbine would operate in the saturated zone. With provision for drainage between the engine and turbine the moisture content in the steam flowing to the turbine should be approximately the same for either of the initial superheats assumed.

### Transmission Efficiencies

Transmission efficiencies for the various arrangements of drive and for the auxiliary high-pressure turbine are given in Fig. 10. No. 3 arrangement is direct acting, and as noted before has no separate transmission mechanism. No. 1 arrangement uses only a set of gears. A constant efficiency of 95 per cent has been assumed for the gear transmission. This value allows for some excess friction due to wear.

All electric drive has been taken as using direct current with a variable generator-voltage control, similar to the Ward Leonard control. This arrangement has worked out well with Diesel-electric drives. It provides high economy combined with a simplified control. In the fourth arrangement there would be a combination of direct drive and electric transmission. For convenience half the power has been considered as electrically transmitted.

In Appendix No. 3 are set down the itemized efficiencies on which the curves of Fig. 10 are based. It will be noted that a higher efficiency is set down for the motor and generator gear transmission than for the gear drive of No. 1 arrangement. This is due to the lower ratio of transmission, the constant speed for the generator, and the lower power rate for the motors. The auxiliary motors are assumed to be direct-current, shunt or compound-wound.

### Thermal Efficiencies

To summarize algebraically, the formulas below show the

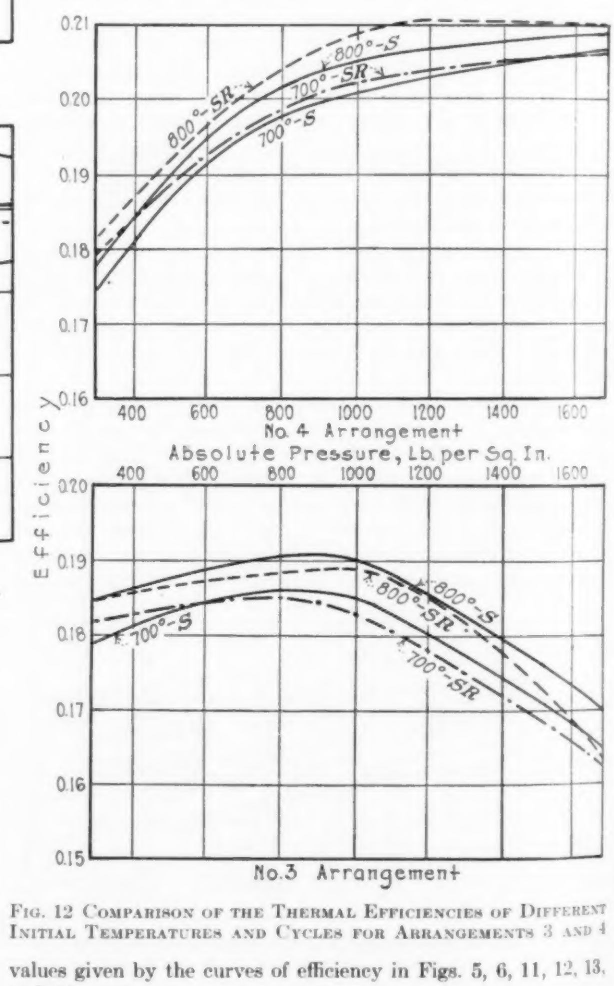

Fig. 12 Comparison of the Thermal Efficiencies of Different Initial Temperatures and Cycles for Arrangements 3 and 4

values given by the curves of efficiency in Figs. 5, 6, 11, 12, 13, and 14.

$$E_c = \frac{N}{H - h} \text{ cyclic efficiency, Figs. 5 and 6.}$$

$$E_t = \frac{N - n_r}{H - h} E_m\, E_a\, E_b, \text{ thermal efficiencies, Figs. 11-14.}$$

where

$N$ = total adiabatic heat drop from admission and reheat to the heaters and condensers

$H$ = total heat in the steam above 32 deg. fahr.

$h$ = total heat in the water at the high-pressure heater outlet, or boiler inlet, above 32 deg. fahr.

$n$ = heat equivalent of power required for the auxiliaries

$E_m$ = machine efficiency

$E_t$ = transmission efficiency

$E_b$ = boiler efficiency, taken at 85 per cent.

The curves of Figs. 11 and 12 illustrate the different efficiencies attainable with the different initial superheats and cycles for each arrangement. For arrangements 1, 2, and 4, which have turbines included, the SR-cycles give in general better results. With No. 3 arrangement the variance is of course relative to the cyclic variance, while with No. 4 the differences are small at the higher and lower pressures.

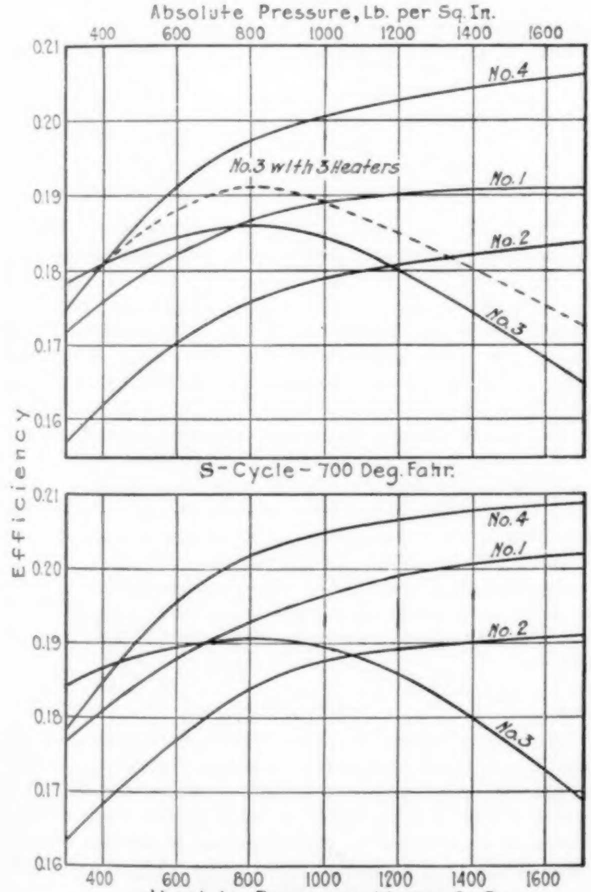

FIG. 13 COMPARISON OF THERMAL EFFICIENCIES FOR DIFFERENT ARRANGEMENTS OF DRIVE WITH THE S-CYCLE

Figs. 13 and 14 compare the efficiencies of all the arrangements for each different initial superheat and cycle. In all cases No. 4 arrangement stands out at the higher pressures above the rest. Apparently the increase in efficiency above 1200 lb. is too small to be attractive in any case. In fact, No. 3 arrangement shows a decrease from approximately 800 lb. Apparently unless the machine efficiency with engine drive could be improved over that estimated, it is improbable that it would pay to generate above 400 or 500 lb. with a complete engine drive. For further comparison, Fig. 13 shows a curve of estimated efficiencies for No. 3 arrangement with three heaters.

The advantages of the combination taken for No. 4 arrangement suggests that the use of a low-pressure turbine for driving the auxiliaries in No. 3 arrangement might improve the total efficiency considerably. The results seem to show, however, that the best all-around combination would be the No. 4 arrangement. No. 1 arrangement on average high speeds such as for through passenger service might be preferable due to the lower first cost. However, present experiences in power stations with gear transmission at the ratio that would be required would indicate that the maintenance for this arrangement might prove too high for economical operation. The trials on locomotives now in use should soon show whether this form of drive will wear.

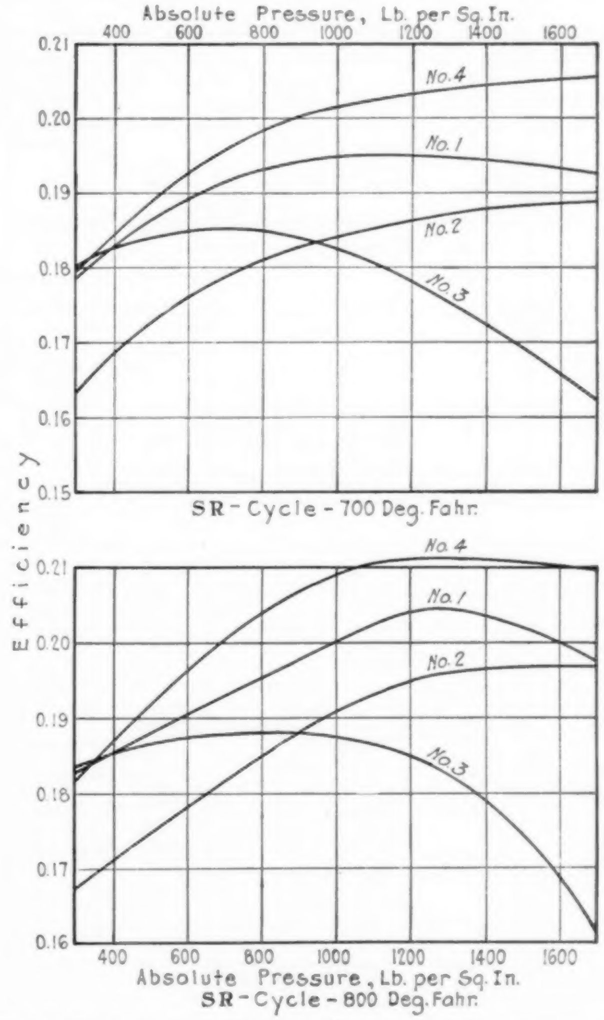

FIG. 14 COMPARISON OF THERMAL EFFICIENCIES FOR DIFFERENT ARRANGEMENTS OF DRIVE WITH THE SR-CYCLES

While No. 2 arrangement shows a lower average efficiency than either No. 1 or No. 4 arrangements, it has certain advantages that for some situations might compensate. Thus it would be possible to arrange the electric equipment so that it could be operated from a trolley or third rail when in an electrified zone. In addition it has an advantage over No. 1 arrangement in tractive characteristics, and over No. 4 arrangement in that the con-

densate would be entirely free from oil contamination. It is probable that the latter feature might allow for the use of open heaters, in which case there would be a possible increase in thermal efficiency.

### Value of Locomotives

Thermal economy as noted in the first part of this paper does not indicate directly the operating economy of a locomotive. For a large portion of the service it has, however, a definite bearing on the total economy. Thus the relative values of locomotives may be said to be determined primarily by the ratio between their average yearly capacity or ton-mileage and the cost of operation. The capacity of a locomotive for heavy freight service varies with its maximum tractive force, its power capacity, its proportional time in service, and its reliability of service.

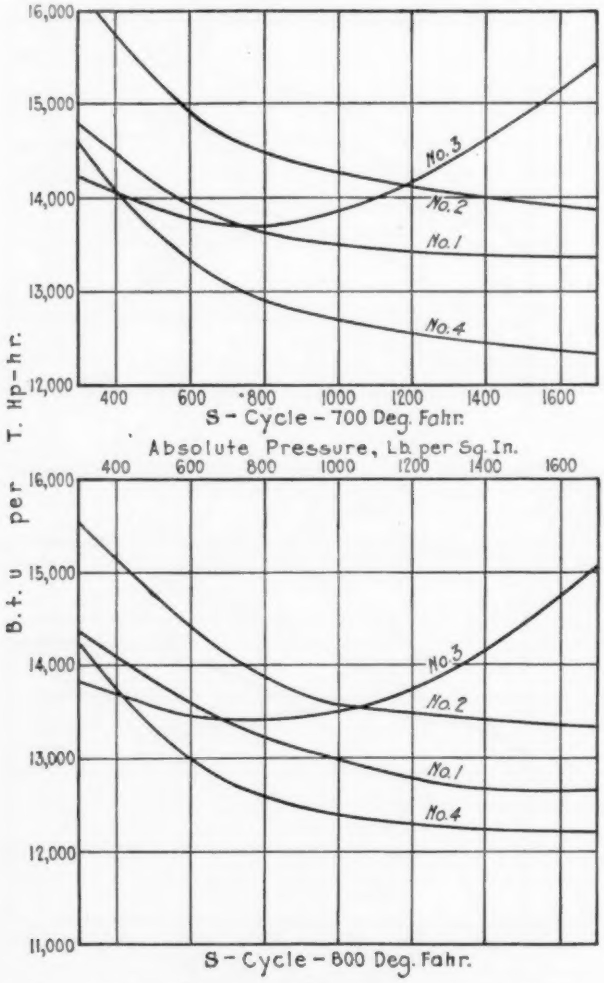

Fig. 15 B.t.u. Required per Tractive-Horsepower-Hour

For the normal speed of freight service, train resistance is nearly constant. Accordingly, an increase in power capacity will provide a nearly direct increase in speed. Or, in other words, the mile-tonnage capacity will be increased directly as the power capacity for any given train. At the same speed an increase in train tonnage would be needed to provide increased locomotive capacity. Increases in train tonnage require increased tractive force as well as increased power capacity. For present conditions it is assumed that the maximum economic train tonnage has been reached. Proportional time in service and reliability of service are matters to be determined by trial. The pressure of operation should not affect these items. The design proposed, with its absence from scale trouble, burnt grates, and its greater simplicity of boiler, should, however, show material improvement in both respects.

With power capacity directly varying as locomotive capacity, it has also been assumed that power capacity will directly depend on thermal efficiency. This would of course hold only for designs approximately the same. Of course the drive design, say a turbine or engine, would need to vary somewhat with the pressure. The boiler and combustion system could, however, be the same regardless of pressure for the type suggested. The efficiency of heat absorption will not enter into the question as long as it is considered constant. It is assumed of course that the best design has been selected. Then as the pressure changes the thermal efficiency will change. Since the thermal output of the boiler is constant, the power capacity must vary as the thermal efficiency. Accordingly the locomotive capacity for the service considered will vary for otherwise constant conditions nearly directly as the thermal efficiency.

Cost of operation of locomotives may be divided as follows:

| | | |
|---|---|---|
| 1 | Fixed charges | 20 per cent |
| 2 | Labor | 18 per cent |
| 3 | Maintenance | 20 per cent |
| 4 | Miscellaneous materials | 8 per cent |
| 5 | Fuel cost | 34 per cent |

This division is tentative and will vary for every difference in operating conditions. The first four items are not here considered as varying with the pressure. They will vary with the design in a greater degree. Fixed charges will vary somewhat, but it is anticipated that the cost will increase with value, though not at the same ratio. The fuel cost or fifth item is given as one-third of the total, which is a fair average for different conditions.

Accordingly, the total locomotive operating value would vary in a four-thirds proportion to its thermal efficiency. On this basis the curves shown in Fig. 17 have been set down. They show the variation in valuation between 350 lb. initial pressure and 1800 lb. for 700 deg. fahr. initial temperature and both the S- and SR-cycles. Only No. 4 arrangement is indicated.

Valuation of locomotives for heavy express passenger service would be on nearly the same basis, though there are other factors involved that would be somewhat different for each territory and run.

### First Cost

No attempt has been made in this paper to compare efficiencies with those attained by present standard locomotives, since the equipment estimated is so different. A comparison of first cost also is of dubious value. The present standard-pressure turbine-driven locomotives built in Europe are said to cost approximately twice the figure for standard construction. These locomotives, however, have been specially built, and it is probable that the cost cited is therefore no criterion of what would prevail if the new designs were built in quantities on a competitive basis. In the type of equipment considered in this article there should be a reduction in cost for parts of the equipment, especially so with a flash or non-water-line boiler such as is indicated in Fig. 18. The condenser proposed would also be much simpler than that used with the locomotives built in Europe.

Re-use of the condensate and better thermal efficiency would reduce the size of tender required. In view of these considerations an estimate of costs has been made (Table 1). This estimate can be compared with the cost of a heavy-duty freight locomotive of recent design equipped with all modern accessories

and built for 250 lb. pressure. The estimate is based on tractive-horsepower capacity and was made up for units of approximately 4000 tractive horsepower, which is about, if not above, the limit for standard units. Costs are estimated for standardized construction, or no allowances are made for special design, and workmanship. On this basis it is felt that the estimates are as nearly correct as can be made without designs.

TABLE 1 ESTIMATED COST OF SUPER-PRESSURE LOCOMOTIVES PER TRACTIVE HORSEPOWER

| | Steam pressures, lb. per sq. in. | | | |
|---|---|---|---|---|
| | 400 | 800 | 1200 | 1600 |
| Arrangement No. 1...... | $30.00 | $31.00 | $33.00 | $36.00 |
| Arrangement No. 2...... | 47.00 | 48.00 | 49.00 | 51.00 |
| Arrangement No. 3...... | 30.00 | 31.50 | 35.00 | 38.00 |
| Arrangement No. 4...... | 40.00 | 41.00 | 42.00 | 43.50 |
| Arrangement No. 4-R.... | 41.50 | 42.50 | 43.00 | 45.00 |

Standard three-cylinder locomotives, 250 lb., $30.00 per tractive horsepower.

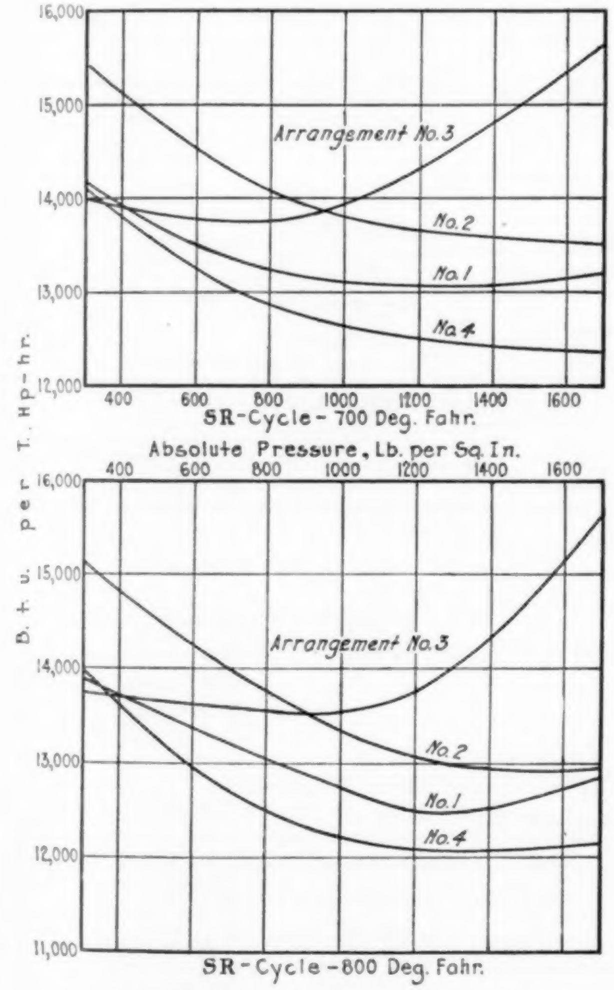

FIG. 16 B.T.U. REQUIRED PER TRACTIVE-HORSEPOWER-HOUR

Increasing pressure only slightly increases the cost except for No. 3 arrangement, the economy of which decreases above 800 to 1000 lb. No inclusion for reheat is made except in an added estimate for No. 4 arrangement marked 4-R. All costs given include the tender.

### Conclusion

The curves of efficiency given can apply to any form of steam generation and with modifications to any form of drive. In setting forth as requisite the types of equipment suggested, safety and practical cost limitations were the main considerations. It is understood that the success of a super-pressure locomotive such as suggested or of any other construction depends on the correct selection and design of several essential details. At the present time it is believed that all the essentials can be solved due to recent advancements in knowledge and practice. It is felt that to obtain the best solution with respect to some of the features involved, tests and operating trials are needed.

## Appendix No. 1

THE proportions of steam discharged to heaters and condensers are taken as I, II, III, etc., respectively.

The heater loss by radiation and ventage plus one is taken as $f$, or for a 5 per cent loss as assumed, $f = 1.05$ in all cases.

Thus

$$\text{I} = \frac{f_1 h_1}{H_1 Q_1} \quad \text{for closed heaters}$$

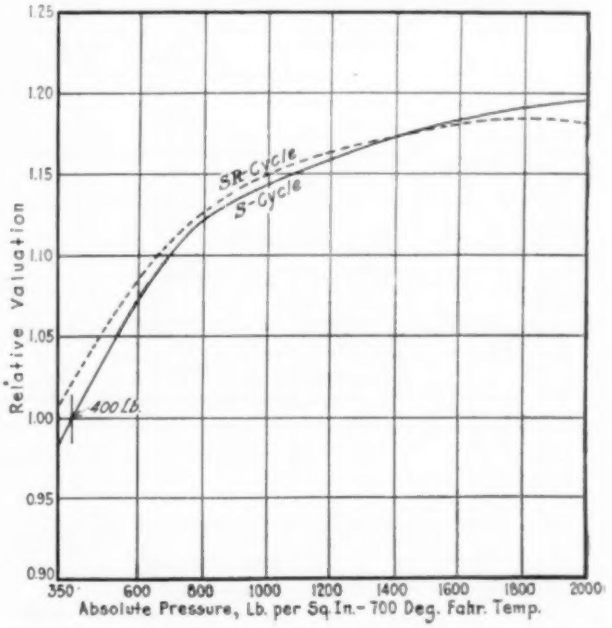

FIG. 17 No. 4 ARRANGEMENT VARIANCE IN LOCOMOTIVE VALUATION BASED ON THERMAL EFFICIENCY

$$\text{II} = \frac{f_2(h_2 - \text{I}h_1)}{H_2 Q_2} \quad \text{etc.}$$

$$\text{III} = \frac{f_3(h_3 - h_2)(\text{I} + \text{II})}{H_3 Q_3} \quad \text{etc.}$$

$$\text{I} = \frac{f_1 h_1}{(H_1 + h_1)Q_1} \quad \text{for open heaters}$$

$$\text{II} = \frac{f_2 h_2(1 - \text{I})}{(H_2 + h_2)Q_2}$$

$$\text{III} = \frac{f_3 h_3[1 - (\text{I} + \text{II})]}{(H_3 + h_3)Q_3} \quad \text{etc.}$$

Where $h$ = heat given to one pound of feedwater in the heater

$H$ = heat in each pound of steam flowing to the heater less the heat per pound of liquid at the heater discharge

$Q$ = quality of the steam flowing to the heater.

In the case of the closed heaters no allowance is made for any heat being given up by the condensed steam below the discharge-water temperature. In well-designed heaters in good condition the drainage should be well below the temperature of the discharge water. In usual practice it is very close to the maximum water temperature.

This heat is considered as used in the heater of lower pressure or for the lowest-pressure heater as discharging to the condenser.

Temperature of heater discharge is taken for closed heaters as 10 deg. fahr. below saturated steam temperature, and for open heaters as 5 deg. fahr. lower.

As here used, $h$ should not be confused with $h$ as used to represent total heat in feedwater at highest-temperature-heater discharge, in the formulas for $E_c$ and $E_t$ given in the paper.

In all cases the pressures given are absolute and the condenser pressure is taken at 2 lb. or 126.1 deg. fahr.

In figuring heater effects the temperature of the supply water was taken at 100 deg. fahr. or 26.1 deg. below condenser steam temperature.

Subscripts indicate heat effect. Thus $h_1$ refers to the heat given to the feedwater in No. 1 or the highest-pressure heater. For two heaters III indicates the proportion of steam entering the condensers. Values I, II, and III include steam and such moisture as would be present due to adiabatic expansion.

*Reheat.* When reheat is added the moisture content in the steam is considered as being evaporated and the total mixture raised to superheated steam at 100 deg. fahr. above the saturated-steam temperature. It is anticipated that a portion of the moisture may be drained off, which would very slightly increase the efficiency, but no allowance is made.

All pressures given are absolute and all temperatures fahrenheit. The temperature of the feedwater supply is taken at 100 deg. fahr. for all cycles, including the Rankine or A-cycle.

TABLE 2 TEMPERATURES OF STEAM TO HEATERS IN DEG. FAHR.

| Steam temperature cycle | Heater No. | Pressure, lb. per sq. in. 400 | 600 | 800 | 1200 | 1600 |
|---|---|---|---|---|---|---|
| 700 deg. S = Cycle | 1 | 294.8 | 306.6 | 317.0 | 327.7 | 358.4 |
| | 2 | 209.6 | 213.0 | 216.3 | 228.0 | 237.8 |
| 800 deg. S = Cycle | 1 | 259.3 | 300.0 | 317.0 | 327.7 | 358.4 |
| | 2 | 193.2 | 209.6 | 216.3 | 228.0 | 237.8 |
| 700 deg. SR = Cycle | 1 | 294.8 | ..... | 317.0 | 327.7 | 358.4 |
| | 2 | 209.6 | ..... | 216.3 | 228.0 | 237.8 |
| 800 deg. SR = Cycle | 1 | 259.3 | 285.8 | 317.0 | 327.7 | 358.4 |
| | 2 | 193.2 | 202.0 | 216.3 | 228.0 | 237.8 |
| 700 deg. S = Cycle | 1 only | 228.0 | ..... | 242.2 | 254.0 | 260.9 |

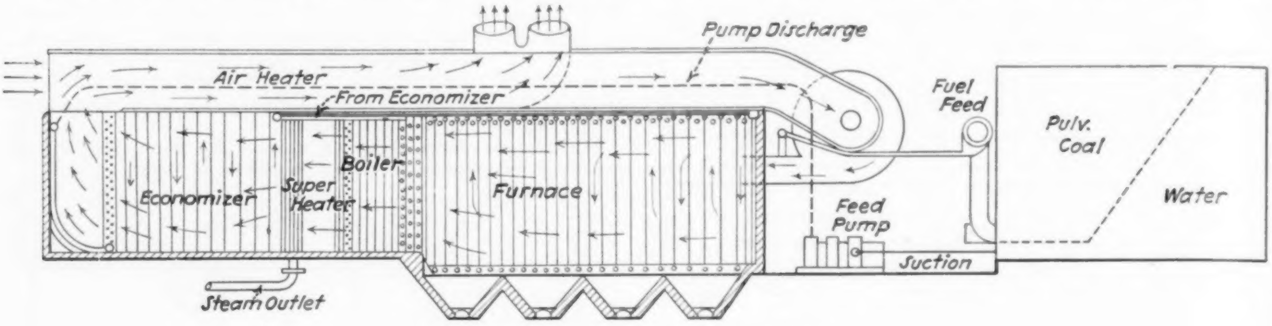

FIG. 18 SUGGESTED BOILER ARRANGEMENT

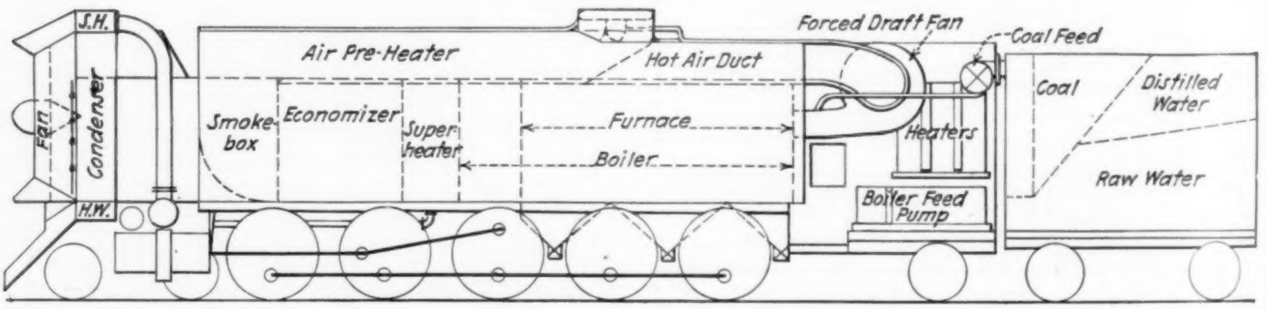

FIG. 19 ARRANGEMENT OF No. 3 DRIVE

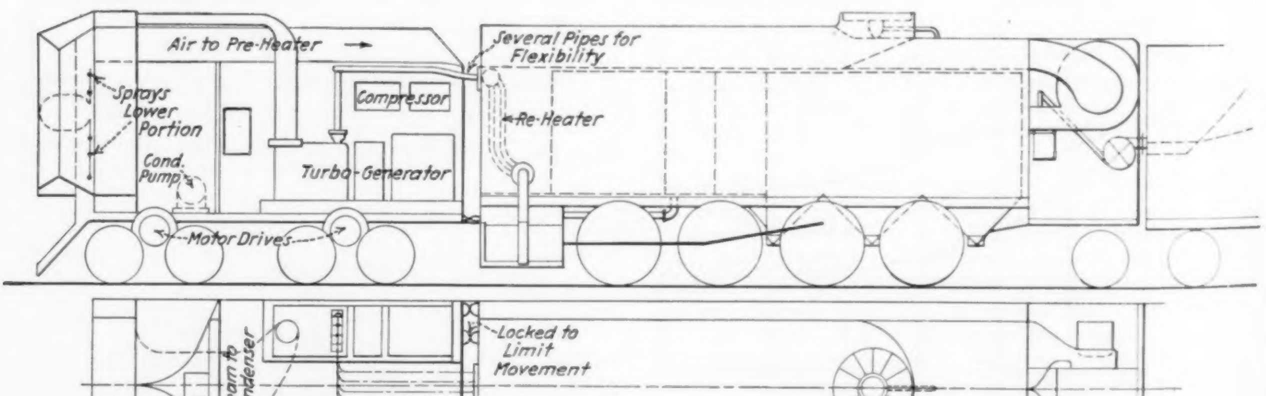

FIG. 20 ARRANGEMENT OF No. 4 DRIVE

## Appendix No. 2

### Boiler-Feed Pump

$$\text{B.t.u. per pound} = \frac{PV \times 144 \times 42.416}{33000 \times 0.60} = 0.00497\,P, \text{ say} = 0.005\,P$$

where $P$ = boiler pressure plus pressure drop through piping and boilers, lb. per sq. in.

$V$ = volume in cu. ft. of 1 lb. of water at suction temperature, say, 100 deg. fahr. = 0.01615. With open heaters $V$ would average higher and the pump efficiency would be lower, but the average quantity of water pumped would be less.

TABLE 3

| Boiler pressure, lb. per sq. in. | Average pressure drops, lb. per sq. in. | Average B.t.u. power equiv. |
|---|---|---|
| 400 | 100 | 2.5 |
| 800 | 100 | 4.5 |
| 1200 | 100 | 6.5 |
| 1600 | 100 | 8.5 |

### Condenser Auxiliary

The condensate pump and air pump are rather small items and have been included among the miscellaneous items.

The work of the fan would vary with the initial temperature and cycle as well as the pressure. An average of the values for each pressure is assumed. This makes the requirements set down for 700 deg. and the *S*-cycle slightly high and for 800 deg. and the *SR*-cycle slightly low.

$$\text{B.t.u. power equiv.} = 0.3175\,W$$

where $W$ = lb. of air per lb. of steam.

Atmospheric temperature = 70 deg. fahr.

Efficiency of fan = 55 per cent.

Static head, average load, = 2 in. of water.

$$W = \frac{H \times \text{III}}{80}$$

where $H$ = heat in each pound of steam entering the condenser above 120 deg. fahr.

III = per cent of total steam flowing to the condenser.

The air at 70 deg. is assumed 60 per cent humidity.

The discharge temperature of the air is assumed to be 120 deg. fahr., with a humidity of 95 per cent.

Then 1 lb. dry air, 70 deg. to 120 deg. fahr. = 12.5 B.t.u.

Evaporation of 0.07185 lb. of water = 69.6 B.t.u.

Raising temp. of 0.07185 lb. of water to 120 deg. fahr. = 3.6 B.t.u.

Total heat absorption per lb. of air = 85.7 B.t.u.

Take . . . . . . . . . . 80

TABLE 4 WEIGHTS OF AIR PER POUND OF STEAM

| Temperature and cycle | Absolute steam pressures, lb. per sq. in. 400 | 800 | 1200 | 1600 |
|---|---|---|---|---|
| 700 deg. fahr. — S | 8.60 | 7.84 | 7.35 | 6.51 |
| 700 deg. fahr. — RS | 9.16 | 8.55 | 8.275 | 7.65 |
| 800 deg. fahr. — S | 9.31 | 8.1 | 7.51 | 6.9 |
| 800 deg. fahr. — RS | 9.745 | 8.65 | 8.35 | 7.75 |
| Average | 9.204 | 8.285 | 7.871 | 7.202 |
| B.t.u. | 2.92 | 2.635 | 2.49 | 2.28 |

### Draft

With 85 per cent boiler efficiency, 6 in. of water per sq. in. average static head, 400 deg. fahr. average temperatures of air and gas through blowers, blower efficiency taken as 60 per cent and weight of gases and air averaged at 15.5 lb. per pound of coal.

With coal at 13,500 B.t.u. per lb., 11,500 B.t.u. to steam per lb. of coal.

$$\text{B.t.u. per lb. of coal} = \frac{V \times 144 \times 6 \times 42.416}{27.7 \times 33{,}000 \times 0.60} = 0.0114 \times 6 \times V$$

$V$ for 15.5 lb. and 400 deg. fahr. = 337

B.t.u. power equiv. = 23.06

| | Absolute steam pressures, lb. per sq. in. 400 | 800 | 1200 | 1600 |
|---|---|---|---|---|
| Lb. of steam, average, for different initial temperatures and cycles, per lb. of coal = | 9.75 | 10.11 | 10.24 | 10.7 |
| B.t.u. per lb. steam = | 2.36 | 2.28 | 2.25 | 2.15 |

TABLE 7 SUMMARY, B.T.U. FOR AUXILIARIES

| Pressure, lb. per sq. in. | 400 | 800 | 1200 | 1600 |
|---|---|---|---|---|
| Boiler-feed pump | 2.5 | 4.5 | 6.5 | 8.5 |
| Condenser | 2.92 | 2.635 | 2.49 | 2.28 |
| Draft | 2.36 | 2.28 | 2.25 | 2.15 |
| Small pumps and miscellaneous | 1.7 | 1.6 | 1.5 | 1.4 |
| Total | 9.48 | 11.015 | 12.74 | 14.33 |

A straight-line variance was assumed for all cases since the results indicated the approximate correctness of that assumption.

## Appendix No. 3

### Transmission

*No. 1 Arrangement—Geared Turbine Drive.* Tests and operation of reduction gearing for powers of from 1000 to 6000 horsepower, and reduction from 15 and 25 to 1 show an average of 97 to 98 per cent efficiency when in perfect condition for stationary drive. When wearing begins the efficiency reduces. For the conditions and service 95 per cent was assumed as a probable average.

*No. 2 Arrangement—Turbo-Generator with Motor Drive.* Generator-voltage speed control, direct current, turbo-generator drive through reduction gears.

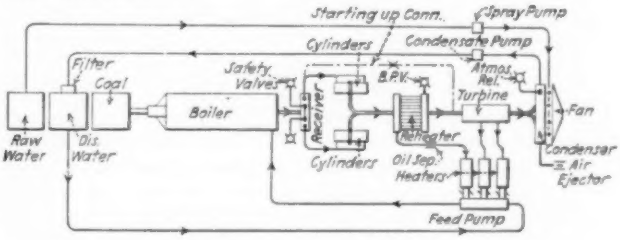

Fig. 21 Diagram of Connections, No. 4 Arrangement

| Loads | 1/4 | 1/2 | 3/4 | full |
|---|---|---|---|---|
| Gearing and generator | 87.00 | 92.0 | 93.0 | 92.0 |
| Motor | 80.00 | 87.0 | 89.5 | 89.0 |
| Motor gearing | 97.00 | 97.0 | 97.0 | 97.0 |
| Total | 67.50 | 77.5 | 80.5 | 79.5 |

*No. 3 Arrangement—Engine Drive Direct Acting.* Transmission 100 per cent efficient.

*No. 4 Arrangement—Engine.* High-pressure and low-pressure turbo-generator.

| | | | | |
|---|---|---|---|---|
| Half load, per cent | 100 | 100 | 100 | 100 |
| Half load, per cent | 66.5 | 76.5 | 79.5 | 78.5 |
| Total average | 83.25 | 88.25 | 89.75 | 89.25 |

Auxiliary Drive, turbo-generator motor:

| Loads | 1/4 | 1/2 | 3/4 | full |
|---|---|---|---|---|
| Turbo-generator gears | 97 | 97 | 97 | 97 |
| Generator | 82 | 85 | 87 | 88 |
| Motors | 75 | 80 | 83 | 83 |
| Total average | 59.5 | 6[illegible] | 70 | 71 |

When the auxiliary generator is on the main shaft the same efficiency of transmission is assumed as for the separate turbo-generator drive.

## Discussion

Lawford H. Fry.[2] The writer has read and heard Mr. Taggart's paper with much interest. In reading it there came to his mind a text which, if memory serves accurately, runs: "Without vision the spirit dieth." It seems to the writer that Mr. Taggart has given us a very interesting vision of what is possible for the steam locomotive of the future. It is a brilliant conception of what we may yet see. Of course we all realize that between conception and independent life there must come a difficult period of considerable length. Before the economies foreshadowed take shape there are many problems of design and construction to be solved, and probably it will be some time before Mr. Taggart's arrangement No. 4 is in active operation.

The economies proposed have been shown to be possible in stationary practice, but when they are to be obtained within the restricted limits allowed the locomotive designer, the difficulties of realization are increased greatly.

[2] Metallurgical Engineer, Standard Steel Works Co., Burnham, Pa. Mem. A.S.M.E.

One feature in particular has caught the writer's attention. Mr. Taggart figures on a boiler efficiency of 85 per cent. This requires a very high efficiency of combustion of the fuel—probably 95 per cent or better. Now, efficiency of combustion is largely dependent on the volume provided for combustion. The paper does not give any dimensions, but by a rough process of scaling it is estimated that the firebox is approximately 8 ft. in diameter and 16 ft. long. This gives about 800 cu. ft. of combustion volume. An output of 4000 horsepower at 1 lb. of coal per horsepower-hour will require the production of 50,000,000 B.t.u. per hour, or about 63,000 B.t.u. per cu. ft. per hour. Such concentrated heat production has been obtained in a few cases in stationary practice, but much lower rates are usual, and unless unusual precautions are taken difficulty with ash and slag removal will be encountered.

L. K. Sillcox.[3] The successful introduction of the high-pressure steam locomotive depends upon a complete, clear, and correct exposition of every known fact surrounding the subject in all of its phases. Mr. Taggart deserves every commendation for the manner in which he has handled the involved problem covered by his excellent paper and the writer will only attempt to briefly state certain requirements in the selection of a design of locomotive which appear to be fundamentally necessary.

Weight limitations are all-important and come increasingly into considerations of design for modern power. Other things being equal, that engine which can develop the most power at the drawbar for the least weight on the rails and at the lowest cost is the one which must in the end hold the greatest favor.

What is required is not only an increase in power of the locomotive itself, but a reduction in maintenance and operating costs, having at the same time regard to the initial cost of the unit itself. With thousands of steam locomotives held idle and in good working order awaiting service at a time of peak business, it is apparent that any new construction offered will need to be sufficiently economical in operation to provide an adequate return to carry its own fixed charges for interest, insurance, taxes, and depreciation, in conjunction with an equal amount to currently retire the value of motive power displaced, otherwise no substantial progress in the way of new construction can reasonably be expected. Undoubtedly locomotive builders are approaching the various railroad administrations along this line. For this reason it is highly desirable that everything possible should be done to encourage every aim toward improvement in construction and design which holds any promise of value.

The principal considerations which have to be taken into account in the development of designs for locomotives are:

1 Maximum service availability
2 Maximum reliability
3 Minimum weight with maximum power, at the drawbar, rear of tender
4 Minimum maintenance expense
5 Minimum fuel and water consumption per unit of service rendered
6 Minimum initial cost consistent with items 1 to 5, inclusive.

The thermal efficiency of the modern locomotive is not high, and there is, for this reason, a large opportunity for the improvement of design and construction in this respect. Financial results do represent the controlling factor, and it is no easy matter to justify the elimination of many so-called obsolete locomotives which are not yet written off the books because of insufficient accumulated depreciation reserve. In the same way it may easily result that one locomotive will develop tractive power on more money (fixed charges and full expense considered) but less coal than another locomotive using more coal but having a lesser investment or fixed charge. What is most needed is a clear conception of what particular design is best suited to the particular service considered, in order to make certain that every advantage has been taken of progress in practice when the locomotive goes into service, and not start a unit in life with a handicap of obsolescence. The very fact that designs are being improved and radically changed from former practice has undoubtedly resulted in a sense of hesitation or caution on the part of purchasers, because of the uncertainty of what future progress holds in store. Sufficient progress has already been made to justify the displacement of almost any locomotive twelve or more years old, provided the service requirements are such as to keep the new unit utilized to a normal degree. Using one's best discretion, which is the superior engine? The problem involves two avenues of measurement. The question is still further confused by the problem of utilization, and one of the main steps toward financial improvement will, undoubtedly, be in the increase of this important value. When this is done, aside from the capacity factor, fuel expense will gain in rank as compared with investment expense.

The locomotive is essentially a power unit, but individual classes of locomotives vary over a wide range of capacity: the high-powered freight unit, as in the 2-8-2 type, or Mikado class, and 2-10-2 type, or Santa Fe class, being those which have been most usually considered for freight service, while the 4-8-4 type, or Hudson class, and 4-8-4 type, or Northern class, are now largely employed for conveying passenger trains.

When high-pressure steam is contemplated and, viewing ultimates, in so far as present outlook permits, we need to realize the existence of a possible strong competitor in the form of the Diesel engine, because the strength of the latter lies in its high thermal efficiency. The steam engine in order to hold its place must achieve economical improvement to a point at which it is in open and reasonable equality with the internal-combustion locomotive. It seems that this equality is promised by high-pressure conditions. When considering comparative performances as a test of success it is necessary to give strict thought to the varying grades of fuel employed in order to arrive at absolute and relative thermal efficiencies. The investment-cost factor may be definitely in favor of the steam locomotive, even with the additions due to the more expensive apparatus for high pressure, and, inasmuch as this feature has a large bearing on operating costs, it should provide an element to be considered when choice of systems is involved.

Reliability of operation is a vital requirement in railroad service, because it involves not only the feature of giving satisfactory service to the public but also influences, to a major degree, the all-important problem, namely, the availability factor of the locomotive as an earning unit. Existing steam locomotives have proved themselves successful in this respect, regardless of maintenance expense to attain this end, and even though there are bound to be some initial difficulties in the application of higher pressures and temperatures, there really should be no ultimate handicap on this account. The feature of properly selecting materials represents the main responsibility in achievement, because high pressures and superheats, through stress action, and the weakening influence of temperature increase the severity of the conditions which the materials have to withstand. The reduced strength of metals at high temperatures is, however, the primary and most definite effect to be considered. The question of materials does decide temperature values, and the same information guides to a very great extent the point of

[3] Assistant to President, N. Y. Air Brake Co., E. Works, Watertown, N. Y. Mem. A.S.M.E.

view with respect to pressure limitations. As operating pressures increase, the necessity for employing steam expansively in the cylinders is made very important and the feedwater problem more serious. The pretreatment of feedwater to remove the hard scale-forming bases by methods that do not produce harmful gases in the steam, is a chemical problem worthy of the most serious attention, while deaeration of the condensate to remove oxygen and other gases that may aid corrosion is really a feature of purely mechanical procedure. With high steam pressures and the possibility of safety valves blowing off, the noise is a real nuisance; and then, again, the feature of having the safety valve close tightly against increased pressures needs due consideration.

When all is said and done, our task is that of producing power, in a practicable way, at the lowest overall cost. This involves not only the conservation of weight and fuel but of capital as well, and the latter is made up of two factors, namely: (1) the price paid for the locomotive, and (2) its probable life.

Charles J. Toth.[4] In the endeavor to develop the steam locomotive to the highest possible state of efficiency, it is fair to assume that it is entirely out of the question to continue with the early tradition. We are simply adding new devices and equipment to a conventional-type mechanical structure which, basically, does not differ from the designs laid down half a century ago.

### Improvement in Power Plants

We are rather faced to attack this important problem on the basis of a general redesign of our conventional-type locomotive, and to this end we must, most logically, follow more closely modern power-plant practice. It is only and exclusively in this field where we can find realized all the structural refinements and, above all, all the perfectly service-tested design features the incorporation of which will be indispensable to build a highly efficient steam locomotive.

In the trend toward adapting to locomotive practice all the approved heat-saving appliances of our modern central stations, of course, due allowance has to be made to all the special problems which arise in locomotive practice owing to conditions peculiar to that service. In the course of this delicate work we shall find that certain difficulties may arise, particularly due to the fact that weight and space are at more of a premium in locomotive design than they are in any other steam plant; but, in the light of present knowledge and experience, the eventual difficulties are by no means insurmountable and require only care in design.

Taking now into thorough account the present power-plant situation and reviewing every detail of the research and development work already done, we see that the very rapid progress of power-plant development seems to have replaced a stage where the station efficiencies were getting close to the ultimate possibilities of the steam cycle generally employed.

With regard to the conventional type of stationary plant, it is now thought that the use of a steam pressure of 1250 lb. per sq. in. represents the ultimate practical limit, and that there can be hardly a practical gain in going to steam pressures in excess of that figure, at least *as long as we resort to the conventional method of steam generation* with all its inherent difficulties due to priming and boiling. In fact, it can be stated with safety that the theoretical gain that can be achieved above this pressure is so small that the cost of getting it is likely to outweigh the small percentage of improvement that can be accomplished.

[4] Montevideo, Uruguay, S. A.

### Super-Pressure Generating System

Fortunately enough, just at the time when the possibilities for a further improved power-plant practice seemed to be beyond the scope of the engineers' ability to solve, there appeared new schemes in the form of the perfection of other than the conventional steam-generating cycles (Atmos, Loeffler, Benson, etc.), and we are now permitted to look with more optimism into the future.

All the pioneer work undertaken in connection with these new schemes and carried out with the purpose of showing that the results which can be expected are reasonably satisfactory, is very well advanced, and all the original claims seem to be completely substantiated. The test results obtained with different experimental plants leave little doubt about the fact that substantially lowered guaranteed fuel consumptions may be obtained and that, finally, we may foresee a theoretical plant efficiency equivalent to a fuel consumption of 7300 B.t.u. per hp-hr. output.

### Super-Pressures for Locomotives

What particularly distinguishes our interest in the subject of the new steam-generating schemes is the fact that, aside from the very low fuel consumption, the new-type plants are of a reduced size and weight, and perhaps owing to their relative simplicity considerably cheaper to build and to maintain than is the case with a conventional-type plant of equal capacity. Hence, in spite of the existing limitations in locomotive design, due to crowded clearance and restrictive weights, it will be easier to adapt to locomotive practice the new super-pressure plants than was the case with the heavier and bulkier conventional-type high-pressure plants.

To appreciate properly the value of the new locomotives, we must, most logically, introduce more up-to-date standards of comparison and scrap certain misconceptions which form the basis from which much erroneous reasoning emanates. Neither must we be hampered by men whose visions cannot extend beyond next year's dividends and who cannot see the future which lies before railway locomotion.

The proposed locomotives will be much costlier to build than any of our present-day locomotives, but if the deciding utility factor, the ton-mile-hour capacity, is examined, the considerably increased earning capacity of the new locomotive becomes most evident, and this item alone justifies part of the 200 to 220 per cent higher cost of construction. If, then, we consider the intensive continuous utilization of the modern power plant and imagine keeping in operation the new locomotives during several days continuously, instead of confining them to six to nine hours' work per day, we can see a single new locomotive replacing two or even three of the conventional-type engines and so fully justifying the increased cost of construction.

Such being the case, all the other items, such as the considerable savings on account of fuel economy (an average of 11,000 B.t.u. per horsepower as against the present figure of 31,000), the lessened boiler troubles owing to the use of pure condensate as feedwater, and, last but by no means least, the lowering of track-maintenance costs due to the greatly improved roadability, will represent additional assets in favor of the new locomotives.

### A Tentative Design of Super-Pressure Locomotive

A tentative design of a super-pressure locomotive, shown in Fig. 22, has been developed on the basis of the following considerations:

As the steam turbine is more readily adaptable to the most severe steam conditions and seems to be, more than any existing reciprocating engine, reliable under extreme working pres-

sures and temperatures, the new design has been developed as a steam-turbine locomotive.

The steam, generated at critical pressure, is throttled to more moderate conditions and its temperature subsequently increased to a proper relative figure. The first expansion is arranged to take place within the stationary nozzles of the primary turbines so as to supply steam of moderate temperature to the impulse blading. In this way the highest temperatures will remain confined to the piping and high-pressure nozzles, these latter conveniently arranged within special chambers mounted separately from the turbine cylinder, except for points of attachments and guides.

will be composed of two power trucks, one carrying the boiler plant, high-pressure turbines, and the principal control organs, and the other carrying the low-pressure turbine, the complete condensing equipment, and the fuel and water tanks.

Owing to the largely fluctuating load characteristics which prevail in railroad operating practice, it is proposed to use oil fuel in order to permit the necessary very flexible fire control. With certain refinement and perfections in the design of the corresponding equipment, it will be possible later to resort to powdered-coal-firing systems.

To provide for the perfect self-contained operation of the plant as a whole, the super-pressure plant will be in direct combination

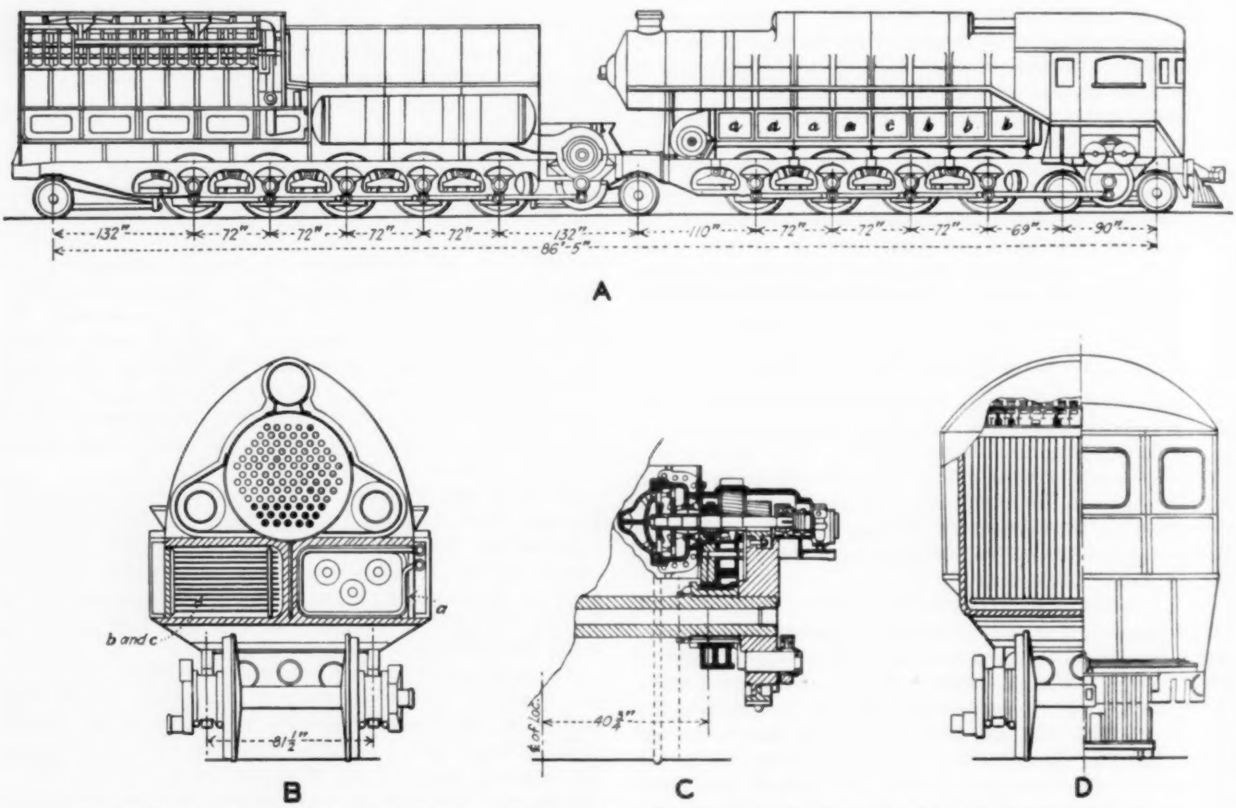

Fig. 22 Elevation and Sectional Views of Proposed Critical-Pressure Condensing Steam-Turbine Locomotive
(*A*—side elevation; *B*—sectional view showing heating tubes; *C*—sectional view of primary turbine; *D*—sectional view showing interstage superheater.)

Compound turbines have been adopted for, among others, the following reasons:

1 The cross-compound arrangement of turbines machinery is less likely to be completely incapacitated and represents, therefore, a greater degree of potential reliability, so essential in railroad work.

2 Further assurance of the greater overall potential reliability lies in the arrangement for the independent operation of any of the prime-mover elements involved.

3 Within a subdivided machinery it is easier to localize any operating trouble.

4 The reheating cycle, so important in any thermal process, becomes more advantageous with subdivided machinery.

5 The compound-turbine arrangement is of utmost importance from the point of view of permitting a greater percentage of the total locomotive weight being utilized as adhesive weight, and, consequently, the attainment of maximum capacity on the adhesive range with a given maximum weight of the locomotive.

In consideration of the foregoing the proposed locomotive with a barrel-type boiler (the cheapest design and permitting a large amount of water reserve with a relatively light-weight boiler structure) designed to carry a steam pressure up to 325 lb. per sq. in.

The critical-pressure generator will consist of bundles of $^{13}/_{16}$-in. inside- and $1^{11}/_{64}$-in. outside-diameter tubes, subdivided into 16 groups with 8 groups located on each side of the locomotive.

In view of the recognized fact that the valuable heat of the furnace is the radiant heat and that it is not productive of best results to reflect it too much back and forth between costly and easily destroyed walls of firebrick, it is proposed to place the tubes constituting the primary evaporative section in the form of a "close screen" near the furnace walls. So the tubes of these sections *a* receive the direct radiating heat of the flame, and at the same time the furnace walls are prevented from heating up to the fusing temperature.

The highly preheated feedwater extracted from the barrel boiler will be delivered by means of a plunger pump, at critical

pressure, to the tube sections *a*. The water enters these tubes at a pressure of 3250 lb. per sq. in. in the front portions of the successive coils, so that operation proceeds on the counter-current principle.

After acquiring a small amount of superheat within the primary coils, thus providing a margin of safety to insure that the critical point is passed before the fluid leaves the coils, the steam will pass through the tube bundles *b* where the evaporation will be completed. The temperature of the steam at the entrance will be about 730 deg. fahr., and at the exit about 790 deg.

The pressure then will be throttled to 1750 lb. and the temperature brought back near the conditions of saturation. Next it will pass through the tubes of sections *c* where its temperature will be again raised, and according to the actual load conditions may reach up to 800 deg. fahr.

The highly superheated steam will expend a portion of its energy within two two-stage primary turbines (one of them shown at *C* in Fig. 1) and will exhaust at about 300 lb. pressure. It is proposed to operate the two primary turbines in series as regards steam flow and in parallel mechanically. Each turbine is to be overhung on its shaft, thus avoiding the necessity of employing high-pressure packings.

The exhaust steam, at about 300 lb. pressure, will be led first through the interstage superheater located at the front portion of the boiler plant (Fig. 22, *D*) in the direct path of the combustion gases where they leave the critical-pressure boiler and, after having been reversed in their direction of flow, will enter the barrel boiler. Here it will be reheated to about 680 to 700 deg. fahr. and then carried to the low-pressure turbine located on the front portion of the tender truck.

A pressure-regulating device incorporated in one of the pressure stages of the main turbine will control the speed of the critical-pressure feed pump, and thus the output of the critical-pressure steam generator. A similar arrangement is being made for the automatic regulation of the air supply and the output of the fuel pump, with the consequent variation in the amount of fuel fed into the main burners. Eventually, with diminishing loads, some of the six main burners may be cut out of operation.

The critical-pressure boiler is being designed to produce up to 12,500 lb. of steam per hour. The tubes of each evaporative section *a* will have 109 sq. ft. of heating surface, hence a total of 872 sq. ft. within the eight sections (four on each side of the locomotive). Within sections *b* and *c* the tubes will be placed horizontally (Fig. 22, *B*), each section's tubes having a heating surface of 308 sq. ft. Thus the distribution of the total heating surface to the different tube sections will be as follows: 8 sections *a*, 872 sq. ft.; 6 sections *b*, 1848 sq. ft.; 2 sections *c*, 616 sq. ft., making a total of 3336 sq. ft.

All connections to the high-pressure tube sections *a*, *b*, and *c* will be located outside the furnace space, within special compartments on both sides of the boiler, and easily accessible. The tube sections of the super-pressure plant are designed for easy and individual removal.

The low-pressure section of the steam-generating plant will consist essentially of a barrel boiler with 100 per cent water and filled completely with fire tubes providing for a total heating surface of 2240 sq. ft. A steam drum is to be located on top of the barrel boiler and extending nearly its full length. The barrel boiler will have two lateral cylindrical portions, each containing a large-diameter fire flue and an auxiliary burner within each flue. In another design the two large-diameter fire flues have been incorporated into the interior of the barrel boiler. The object of this arrangement is to provide means for the independent generation of 325-lb. steam in the event that the super-pressure generator be out of commission.

It is intended that the auxiliary burners shall enter into operation only for the generation of the steam necessary to start the operation of the super-pressure boiler. But, of course, this arrangement provides also for the possible operation of the locomotive as a 325-lb. pressure-turbine locomotive, if required through the unlikely event of a complete failure of the critical-pressure plant. In the latter event the 325-lb. steam will be superheated within the coils, which, in ordinary operation, will serve as interstage reheaters of the working steam. It may be added that in this form of operating the locomotive, the tubing of the super-pressure plant will not come into direct contact with the combustion gases leaving the auxiliary burners.

The interstage superheater (left-hand portion of Fig. 22, *D*) will be built up of $^{13}/_{16}$-in.-diameter tubes placed vertically and expanded into cylindrical headers. Appropriate extensions on the headers will contain all the necessary valves for the control of the following alternate methods of operation:

1 Give free passage for the working steam between the primary and low-pressure turbines without the addition of steam from the barrel boiler.

2 The same function as under 1 with the difference that steam is added from the barrel boiler to the interstage steam in varying amounts according to the momentary load conditions.

3 Cut off the communication between the primary and low-pressure turbines and admit steam direct from the barrel boiler for the operation of the low-pressure ahead turbine.

4 As under 3 with the difference that the steam admitted is for the operation of the low-pressure reversing turbine.

No high-pressure reversing turbines are specified, the idea being to avoid the necessary arrangement of duplicate high-pressure turbines or else the arrangement of reversing gear.

To lessen the necessity for the operation of the auxiliary burners, the following arrangement has been adopted:

A bypass in the 1750-lb. steam piping between the primary turbines and the steam generator will be provided. During the periods of stopping the primary turbines, the critical-pressure plant will be kept operating, at a lower or the lowest possible rate of output, and the highly superheated steam thus generated admitted to a series of heating elements located within the lower portion of the barrel boiler. Within these elements the live steam will first be desuperheated and then expanded by means of adequate nozzles down to the pressure existing within the barrel boiler, and its heat content completely exchanged with the water content of the barrel boiler.

All prime movers are designed for a maximum speed of 8900 r.p.m. and are provided with exactly identical double-reduction gearing of a ratio of 1:24. The design of the primary turbines has already been indicated and is shown in Fig. 22, *C*. The low-pressure turbine consists of a two-stage impulse wheel and nine rows of reaction blading for the ahead turbine. On the same shaft is provided a two-stage impulse wheel and four rows of reaction blading for the reversing turbine.

Of course, with a view of cutting costs it would be perfectly feasible to adopt the complete low-pressure turbine, condensing equipment and auxiliaries of one of the perfectly service-tested turbine locomotives and dispose all this equipment on a tender truck. (Either the Zoelly of the Ljungström locomotive equipment is available.) Such a truck would then be combined with one carrying the steam generator and the primary turbines, etc. Since little experimentation is necessary with the above-mentioned low-pressure turbine equipment, the expenses would be confined to experiments with the super-pressure machinery. Thus the proceedings which are being adopted with good results in experimental super-pressure central stations would be followed.

The framing of both trucks, located outside the wheels, is cast in one piece with all necessary transverse members and

bedplates. The manner of coupling the two trucks together through the use of a pivot pin and a pony truck is indicated in Fig. 22, *A*.

It is not considered necessary to give at present a more detailed description of the condensing equipment, as this is supposed to be well known from data on the many existing turbine locomotives. However, the writer would state that he is inclined to favor the application of a surface-condenser system, as this type of equipment is much less delicate than the evaporating-type condenser. The method of recooling the circulating water is the well-known sprinkler system.

The general arrangement of the auxiliaries inherent to the condensing equipment also need not be described, as this is the same as employed on existing turbine locomotives. However, attention may be directed to the application of a duplicate draft arrangement. An induced-draft fan, turbine-driven, is located at the left end of the smokebox, and a forced-draft fan is located beneath the smokebox. The turbine drive of the latter is in direct combination with the drive of the fuel pump so that the output of the fuel is automatically adjusted to the amount of of preheated combustion air delivered to the burner castings. The forced-draft fan draws the combustion air through the preheater which is located within the smokebox and has a total heating surface of 1850 sq. ft.

No feedwater heater is provided, the waste heat in the flue gases being restored to the system by means of the air preheater.

The pure condensate available for the boiler feed is preheated by means of the steam exhausting from the engine driving the critical-pressure plunger pump and from the turbines driving the draft fans.

The critical-pressure plunger pump is located within a special compartment of the cab, where it is as convenient as any of the principal steam control valves.

As regards the location of the cab at the front end of the locomotive, the writer believes little discussion as to the advantages is necessary. It appears illogical to impose ever greater responsibility upon the engineman and in addition confine him behind a 30-ft. to 50-ft. boiler structure of excessive cross-sectional area where he remains bereft of the clear vision so essential from the standpoint of safety in train operation.

## Conclusions

Railway authorities who are conscientiously aware of their great responsibilities should take into consideration all the ways and means available to bring the steam locomotive to the highest possible state of efficiency. If they come to the conclusion that the adaptation of some service-tested method will really bring about important advantages in operating efficiency and economy there is no necessity for insisting on going step by step through all the possible intermediate and less efficient development stages. We are perfectly justified in making an important unconventional jump forward, the more so because it brings us nearer to the desired goal. In this the writer believes all interested parties will concur.

From the standpoint of an impartial judgment it may be stated with safety that there is nothing freakish about the realization of a critical-pressure locomotive, because actual practice has taught us how to control with reasonably satisfactory results steam of extreme pressure and temperature conditions. Moreover, it is well to keep in mind the fact that for a long time hydraulic and pneumatic plants have been in successful operation at pressures of several thousands of pounds per square inch.

In our internal-combustion engines, in addition to high pressures we also encounter temperatures far in excess of those contemplated within the proposed super-pressure locomotive.

Why then should we have doubts about the possible perfect control of high pressures and temperatures within the proposed new steam locomotives?

The means for the proper construction and control of the new machinery are at hand—it remains then to understand, or rather be willing, to utilize them properly. Realizing this, we can be confident that development will not stop with the present state of the art of producing power for rail transportation. However, the future is entirely dependent upon the question of finding some progressively minded railroad operator who neither lacks the imagination in gaging the immediate and future possibilities nor the courage to decide in favor of the application of new schemes to actual installations.

TABLE OF DIMENSIONS AND WEIGHTS

| | | |
|---|---|---|
| Type of locomotive | | 4-8-2-10-2; (2-D-1-E-1) |
| Speed of turbines at the maximum locomotive speed of 63 m.p.h. | | 8900 r.p.m. |
| Diameter of driving wheels | | 57 in. |
| Weights in working order | Adhesive weight | 554,600 lb. |
| | Front truck | 69,200 lb. |
| | Central truck | 58,000 lb. |
| | Trailing truck | 42,800 lb. |
| Total weight of locomotive | | 724,600 lb. |
| Total wheelbase | | 86 ft. 5 in. |
| Maximum rigid wheelbase | | 18 ft. |
| Capacity of the critical-pressure generator | | 12,500 lb. per hr. |
| Capacity of cooling-water tanks | | 90,000 lb. |
| Capacity of feedwater tanks | | 24,000 lb. |
| Capacity of fuel-oil tanks | | 24,000 lb. |
| Combined output of the critical- and low-pressure turbines | | 3,500 hp. |
| Tractive effort | | 168,000 lb. |

## Author's Closure

The paper as presented is intended to be complete in itself. For a full understanding of the author's viewpoint, however, it is necessary to consider it in conjunction with the articles referred to therein, namely, those published in the September and October, 1927, issues of the *Railway Mechanical Engineer*. In those articles many of the questions brought up by Mr. Fry and Mr. Sillcox are dealt with.

Mr. Fry's estimate of the furnace volume available is, the author believes, about correct. It is the same as was given in the latter's article in the September issue of the *Railway Mechanical Engineer*. The efficiency, 85 per cent, however, was taken for an average loading which was assumed in the article as between one-half and three-fourths maximum. Taking 4000 hp. as the average load would therefore give a maximum load of about 6400 hp. at the same rate or, say, 6000 hp. at a reduced efficiency. This is a higher power than the author assumed for a furnace volume of 800 cu. ft. Considering all the conditions assumed, it is his belief that the efficiency of 85 per cent is conservative. It should be remembered that this efficiency is not for the boiler alone but includes the performance of the economizer, superheater, and air preheater. It also includes fine pulverization, turbulent burners, and a furnace equipped with suitable slag screens.

Mr. Sillcox in his discussion brings up some of the defects of the present locomotive, such as high maintenance, relatively low service availability, large weight relative to the tractive force and power capacity, and low efficiency. It is evident that any design departing from standard practice must be an improvement in these respects to be of value. The author feels that in all the ways mentioned a high-pressure condensing locomotive can be produced that will be a material improvement over present practice. The first cost of a locomotive to accomplish this should not materially increase the fixed charges. It is evident, however, that for the design advanced, pulverizing and make-up water evaporating plants would be required and new maintenance equipment would be needed. To make this worth while the increase in economy must be large.

At the present time the steam-driven locomotive, even with its low efficiency, has not a very much higher fuel charge than would

be required for a Diesel drive at the present cost of oil. This would hold for average conditions in this country. In addition a large use of fuel oil could be depended upon to jump the price considerably. It appears to the author that for general use it would be more promising to attempt to develop the steam drive to an efficient basis. Below he gives a comparison of power costs for Diesel and steam drives.

| Locomotive | Efficiency, per cent | Power, B.t.u. for 1 cent |
|---|---|---|
| Present standard | 7 | 7,000 |
| High-pressure condensing | 20 | 18,000 |
| Present Diesel-engine drive | 25 | 7,280 |
| Improved Diesel-engine drives (est.) | 33 | 9,600 |

These figures are based on coal at $2.66 per ton with an allowance of 10 per cent additional for pulverizing in the case of high-pressure condensing steam locomotives. Oil is considered at approximately 0.6 cent per lb. The price of the coal used is the average cost to the railroads during one of the recent years. The price of fuel oil is the approximate present price delivered at a water terminal. Both will vary, depending on location. At the present time it appears to be feasible to develop high-pressure condensing steam locomotives with a thermal efficiency equal to that set down. Manufacturers in Europe, it is understood, will now guarantee certain types of standard-pressure turbine condensing locomotives to have 17 per cent thermal efficiency.

# Vibration of Bridges

By S. TIMOSHENKO,[1] ANN ARBOR, MICH.

*It is well known that a rolling load produces in a bridge or in a girder a greater deflection and hence greater stresses than the same load acting statically. This "impact effect" of live loads on bridges is of great practical importance. In this paper the following kinds of impact are analyzed:*

*1 "Live-load effect" of a smoothly running load*
*2 "Impact effect of balance weights" of locomotive driving wheels*
*3 "Impact effect due to irregularities." These irregularities include irregularities in the track and also flat spots on wheels.*

*It is shown that the "live-load effect" of a smoothly running load is small and can be always neglected. The "impact effect of balance-weights" may be of considerable importance, especially under conditions of resonance, and is most severe on bridges of the shortest span which will allow resonance conditions to occur. For the assumptions made in this paper the minimum length of the span to allow such resonance will be about 100 ft.*

*The "impact effect due to irregularities" of track may attain considerable magnitude in the case of short girders and rail bearers. By removing such discontinuities in the track as rail joints a considerable decrease in impact stresses produced in bridge parts directly subjected to the dynamical effect of moving wheels can usually be accomplished.*

It is well known that a rolling load produces in a bridge or in a girder a greater deflection and greater stresses than the same load acting statically. Such an "impact effect" of live loads on bridges is of great practical importance, and many engineers have worked on the solution of this problem.[2] There are various causes for these impact effects, and in the following

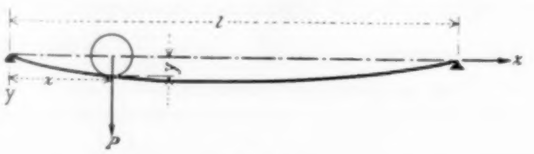

Fig. 1

such impact effects as (1) "live-load effect" of a smoothly running load, (2) "impact effect of the balance weights" of the locomotive driving wheels and (3) "impact effect due to irregularities," which includes irregularities in the track and flat spots on wheels, are discussed.

### Live-Load Effect of a Smoothly Running Mass

In discussing this problem two extreme cases are considered: (1) the mass of the moving load large in comparison with the mass of the bridge, and (2) the mass of the moving load small in comparison with the mass of the bridge. In the first case the mass of the bridge, can be neglected. Then the deflection of the bridge under the load at any position of this load will be proportional to the pressure $R$ which the rolling load $P$ produces on the beam (Fig. 1), and can be calculated from the known equation of statical deflection

$$y = \frac{Rx^2(l-x)^2}{3lEI} \qquad [1]$$

in which $EI$ = flexural rigidity of the beam. Other notations are given in Fig. 1. In order to obtain the pressure $R$ the inertia force $-\frac{P}{g}\frac{d^2y}{dt^2}$ should be added to the rolling load $P$. Assuming that the load is moving along the beam with a constant velocity $v$, we obtain

$$\frac{dy}{dt} = \frac{dy}{dx}\frac{dx}{dt} = v\frac{dy}{dx} \qquad \frac{d^2y}{dt^2} = v^2\frac{d^2y}{dx^2}$$

The inertia force becomes $-\frac{P}{g}\frac{d^2y}{dt^2} = -\frac{P}{g}v^2\frac{d^2y}{dx^2}$, and the pressure on the beam will be

$$R = P\left(1 - \frac{v^2}{g}\frac{d^2y}{dx^2}\right) \qquad [2]$$

Substituting in Equation [1] we obtain

$$y = P\left(1 - \frac{v^2}{g}\frac{d^2y}{dx^2}\right)\frac{x^2(l-x)^2}{3lEI} \qquad [3]$$

This equation determines the trajectory of the point of contact of the rolling load with the beam.[3] A good approximation for the solution of Equation [3] will be obtained by assuming in calculating the inertia force that the deflections are the same as at zero speed ($v = 0$). The value

$$\frac{Px^2(l-x)^2}{3lEI}$$

may therefore be substituted for $y$ in the right side of this equation. Then by simple calculations it can be shown that $y$ becomes a maximum when the load is at the middle of the span, and the maximum pressure will be

$$R_{\max.} = P\left(1 + \frac{v^2}{g}\frac{Pl}{3EI}\right) \qquad [4]$$

The maximum deflection in the center of the beam increases at the same rate as the pressure on it, so that

$$\delta_d = \delta_{st}\left(1 + \frac{v^2}{g}\frac{Pl}{3EI}\right) \qquad [5]$$

This approximate solution, as compared with the result of an exact solution of Equation [3],[4] is accurate enough for practical applications. The additional term in the brackets is usually very small, and it can be concluded that the "live-load effect" in the case of small girders has no practical importance.

In the second case, when the mass of the load is small in comparison with the mass of the bridge, the moving load can be replaced with sufficient accuracy by a moving force. The problem then consists of determining the vibrations of the bridge produced by a vertical force $P$ moving along the bridge with a constant velocity $v$. The complete solution of this problem is

[1] Engineering Mechanics Department, University of Michigan, Ann Arbor, Mich., Mem. A.S.M.E.

[2] The history of the subject is extensively discussed in the famous book by Clebsch. Translated by S. Venant (Paris, 1883). See Note of § 61, p. 597.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers.

[3] This equation was established by Willis, Appendix to the Report of the Commissioners to inquire into the Application of Iron to Railway Structures (1849), London.

[4] The exact solution of the Equation [3] was obtained by G. G. Stokes. See Math. and Phys. Papers, vol. 2, p. 179.

given in the Appendix. It is there shown—see Equation [43]—that the amplitude of vibration depends on the value of the ratio:

$$\alpha = \frac{T}{2T_1} \qquad [6]$$

where $T$ = natural period of vibration of the bridge, and
$T_1$ = time it takes the force to pass over the bridge.

Taking the most unfavorable assumption regarding the superposition of statical deflection and deflection due to vibration, and neglecting damping, the following equation for maximum deflection produced by a moving force $P$ will be obtained (see Appendix).

$$\delta_d = \frac{\delta_{st}}{1 - \alpha} \qquad [7]$$

in which $\delta_d$ = maximum dynamical deflection, and
$\delta_{st}$ = the deflection produced by the same force when applied at the middle.

The value of the quantity $\alpha$ is usually small; therefore the dynamical effect of a smoothly running load is usually negligible. Let us take as an example three bridges of different spans $l$ = 60 ft., $l$ = 120 ft., and $l$ = 360 ft. The approximate values of the periods $T$ of natural vibrations are given in the second line of the table below. In the third line of the same table the time $T_1$ for the load to pass over the bridge ($v$ = 120 ft. per sec.) is given, while in the fourth line we have the calculated values of the ratio $\alpha = T/2T_1$. The largest effect of running load is thus obtained for the smallest span and from the table it can be concluded that for this span and with a very high velocity the increase in deflection due to the live-load effect is about 12 per cent, and this is still diminished with decrease in velocity and with increase in length of span.

| | | | | |
|---|---|---|---|---|
| $l$ | = | 60 ft. | 120 ft. | 360 ft. |
| $T$ | = | $^1/_9$ | $^1/_5$ | $^1/_2$ |
| $T_1$ | = | $^1/_2$ | 1 | 3 |
| $\alpha = \frac{T}{2T_1}$ | = | $^1/_9$ | $^1/_{10}$ | $^1/_{12}$ |

If several moving loads are acting on the bridge the oscillations associated with these should be superimposed. Only in the exceptional case of synchronized vibrations will the resultant live-load effect on the system be equal to the sum of the effects of the separate loads and the increase in deflection due to this effect be in the same proportion as for a single load. From these examples it can be concluded that the live-load effect of a smooth-running load is not an important factor, and even in the most unfavorable cases it will hardly exceed 10 per cent. Much more serious effects may be produced, as we shall see now, by the pulsating forces produced by the rotating balance weights of steam locomotives.

### Impact Effect of Balance Weights

The most unfavorable condition occurs in the case of resonance when the number of revolutions per second of the driving wheels is equal to the natural frequency of vibration of the bridge. For a short-span bridge the natural frequency is usually so high that synchronism of pulsating load and natural vibration is impossible at any practical velocity. By taking, for instance, six revolutions per second of the driving wheels as the highest limit and taking the frequencies of natural vibration from the table above, it can be concluded that the resonance condition is hardly possible for spans less than 100 ft. in length. For longer spans resonance conditions should be taken into consideration, and the impact effect should be calculated on this assumption.

The complete discussion of forced vibrations produced by balance weights is given in the Appendix; here the application of the final equation (see p. 8) only will be shown.

Let $P_1$ = maximum resultant pressure on the rail due to the counterweights when the driving wheels are revolving once per second

$\frac{P_1}{T^2}$ = resultant pressure on the rail when the number of revolutions of the wheel per second is equal to natural frequency $1/T$ of the bridge

$n$ = total number of revolutions of the driving wheels during passage along the bridge.

Then from Equation [45], given in the Appendix, we obtain the following additional deflection due to the impact effect of driving wheels:

$$\delta_{max.} = \frac{2n}{T^2}\frac{2P_1l^3}{EI\pi^4} \qquad [8]$$

It is seen that in calculating the impact effect due to balance weights such quantities as (1) the statical deflection $\frac{2P_1l^3}{EI\pi^4}$ produced by the force $P_1$, (2) the period $T$ of the natural vibration of the bridge, and (3) the number of revolutions $n$ should be taken into consideration. All these quantities are usually disregarded in impact formulas as applied in bridge design.

In order to obtain an idea of the amount of this impact effect let us apply Equation [8] to a numerical example[5] of a locomotive crossing a bridge of 120 ft. span. Assuming that the locomotive load is equivalent to a uniform load of 14,700 lb. per linear foot distributed over a length of 15 ft., and that the train load following and preceding the locomotive is equivalent to a uniformly distributed load of 5500 lb. per linear foot, the maximum central deflection of each girder is $\frac{2l^3}{EI\pi^4}(275{,}000)$, approximately. The same deflection when the locomotive approaches the support and the train completely covers the bridge is $\frac{2l^3}{EI\pi^4}(206{,}000)$, approximately. Taking the number of revolutions $n$ = 8 (the diameter of the wheels being equal to 4 ft. 9 in.) and the maximum pulsating pressure on each girder at the resonance condition equal to $\frac{P_1}{T^2}$ = 18,750 lb., the additional deflection, calculated from Equation [8] will amount to

$$\frac{2l^3}{EI\pi^4}\ (300{,}000)$$

Adding this to the statical deflection, calculated above for the case of the locomotive approaching the end of the bridge, we obtain the complete deflection at the center equal to $\frac{2l^3}{EI\pi^4}$ (506,000). Comparing this with the maximum statical central deflection $\frac{2l^3}{EI\pi^4}$ (275,000), given above, it can be concluded that the increase in deflection due to impact is, in this case, about 84 per cent. Assuming the number of revolutions $n$ equal to 6 (the diameter of driving wheels equal to $6^1/_2$ ft.) and assuming again a condition of resonance, we obtain for the same numerical example an increase in deflection equal to 56 per cent.

In the case of bridges of shorter spans, where the natural frequency of vibration is considerably higher than the number of revolutions per second of the driving wheels, a satisfactory

[5] The loading conditions following are taken the same as in the paper by C. E. Inglis. See Proc. Inst. of Civil Engineers, vol. 218 (1924), London.

approximation can be obtained by using the general solution, Equation [44], given in the Appendix. By taking only the first term of this solution and assuming the most unfavorable condition, we arrive at Equation [46], which must be used in this case.

Consider, for instance, a 60-ft-span bridge, and assume the same kind of loading as in the previous example, then the maximum statical deflection is $\frac{2l^3}{EI\pi^4}$ (173,000), approximately. If the driving wheels have a circumference of 20 ft. and make 6 revolutions per second, the maximum downward force on the girder will be $18{,}750\left(\frac{6}{5}\right)^2 = 27{,}000$ lb. Assuming the natural frequency of the bridge equal to 9, we obtain, from Equation [46],

$$\delta = \frac{2l^3}{EI\pi^4}\,(27{,}000 \times 2.57) = \frac{2l^3}{EI\pi^4}\,(69{,}400)$$

hence

$$\frac{\text{dynamical deflection}}{\text{statical deflection}} = \frac{173 + 69.4}{173} = 1.40$$

The impact effect of the balancing weights in this case amounts to 40 per cent.

In general, it will be seen from the theory developed that the most severe impact effects will be obtained in the shortest spans for which a resonance condition may occur (about 100-ft. spans for the assumption made above), because in this case the resonance occurs when the pulsating disturbing force has its greatest magnitude. With increase in the span the critical speed decreases, and also the magnitude of the pulsating load; consequently the impact effect decreases.

For very large spans, when the frequency of the fundamental type of vibration is low, synchronism of the pulsating force with the second mode of vibration having a node at the middle of the span becomes theoretically possible. Therefore, due to this cause an increase in impact effect may occur at a velocity about four times as great as the first critical speed.

It should be noted that all our calculations have been based on the assumption of a pulsating force moving along the bridge. Under actual conditions we have rolling *masses*, which will cause a variation in the natural frequency of the bridge in accordance with the varying position of the loads. This variability of the natural frequency, which is especially pronounced in short spans, is very beneficial because the pulsating load will no longer be in resonance all the time during passage over the bridge, and its cumulative effect will not be as pronounced as is given by the above theory. From experiments made by the Indian Railway Bridge Committee[6] it is apparent that, on the average, the maximum deflection occurs when the engine has traversed about two-thirds of the span, and that the maximum impact effect amounts to only about one-third of that given by Equation [8]. It should be noted also that the impact effect is proportional to the force $P_1$, and therefore depends on the type of engine and on the manner of balancing. While in a badly balanced two-cylinder engine the force $P_1$ may amount to more than 1000 lb.,[7] in electric locomotives perfect balancing can be obtained without introducing a fluctuating rail pressure. This absence of impact effect may compensate for the increase of axial weight in modern heavy electric locomotives.

In the case of short girders and rail bearers whose natural frequencies are very high, the effect of counterweights on the deflection and stresses can be calculated with sufficient accuracy by neglecting vibrations and using the statical formula in which the centrifugal forces of counterweights should be added to the statical rail pressures. The effect of these centrifugal forces may be especially pronounced in the case of short spans when only a small number of wheels can be on the girder simultaneously.

[6] See Bridge Sub-Committee Reports, 1925, Calcutta: Government of India Central Publication Branch, Technical Paper No. 247 (1926).

[7] Some data on the values of $P_1$ for various types of engines are given in the Bridge Sub-Committee Report, mentioned above.

### Impact Effects Due to Irregularities of Track and Flat Spots on Wheels

Irregularities such as rail joints, low spots on the rails, or flat spots on wheels, etc., may be responsible for considerable impact effect which may become especially pronounced in the case of short spans. If the low spots in the track or the flat spots on the wheels have the shape of a smooth curve, the same method as used in the analysis of track stress[8] can be applied here also. The following analysis for obtaining the maximum dynamical effect assumes a rigid track, the flexibility being neglected. Let the equation

$$y = \frac{\delta}{2}\left(1 - \cos\frac{2\pi x}{l}\right) \qquad [9]$$

represent the shape of a low spot on a rail, shown in Fig. 2. If

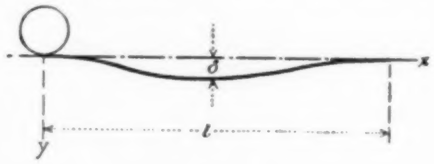

Fig. 2

a wheel of the mass $P/g$ is moving along this curve with a constant velocity $v$, the velocity of the load in the vertical direction will be

$$\frac{dy}{dt} = \frac{dy}{dx}\frac{dx}{dt} = v\frac{dy}{dx}$$

and the corresponding acceleration is

$$\frac{d^2y}{dt^2} = v^2\frac{d^2y}{dx^2}$$

Substituting [9] for $y$ we obtain

$$\frac{d^2y}{dt^2} = \frac{4\pi^2}{l^2}\frac{\delta v^2}{2}\cos\frac{2\pi x}{l}$$

The inertia force, which must be added to the statical load $P$ and which represents the dynamical effect in this case, will be

$$-\frac{P}{g}\frac{d^2y}{dt^2} = -\frac{P}{g}\frac{4\pi^2}{l^2}\frac{\delta v^2}{2}\cos\frac{2\pi x}{l}$$

The maximum value of the additional pressure on the rail due to this inertia force of the moving wheel will be obtained when $x = \frac{l}{2}$ and $\cos\frac{2\pi x}{l} = -1$. Then

$$\left(-\frac{P}{g}\frac{d^2y}{dt^2}\right)_{\text{max.}} = \frac{P}{g}\frac{4\pi^2}{l^2}\frac{\delta v^2}{2} \qquad [10]$$

It is seen that the additional pressure will be proportional to the unsprung mass of the wheel, to the square of the velocity of the train, and to the ratio $\delta/l^2$. This pressure may attain a considerable magnitude, and is therefore of practical importance in the

[8] See "Applied Elasticity," by S. Timoshenko and J. M. Lessells, p. 334.

case of short bridges and rail bearers. This additional dynamical effect produced by irregularities in the track and flats on the wheels justifies the high impact factor usually applied in the design of short bridges. By removing rail joints from the bridges and by using ballasted spans or those provided with heavy timber floors, the effect of these irregularities can be diminished and impact stresses correspondingly decreased.

### Conclusions

From the above analysis it is seen that the "live-load effect" of a smoothly running load is always small. Under the most unfavorable condition it will not exceed 10 per cent, and can therefore be neglected.

The "impact effect of the balance weights" of the locomotive driving wheels may become of practical importance, especially under conditions involving resonance. The most severe impact effect will be obtained in the shortest spans in which resonance is likely to occur. For the assumptions made in this paper this span is about 100 ft.

The additional dynamic effect produced by irregularities in the track and flats on the wheels is of importance only for bridge parts directly subjected to the action of moving loads, and justifies the high impact factor usually applied in the design of short girders and rail bearers.

## Appendix

### General

IN DISCUSSING vibrations of bridges the problem can be simplified by considering the bridge as a beam of uniform cross-section simply supported at the ends. The general form of de-

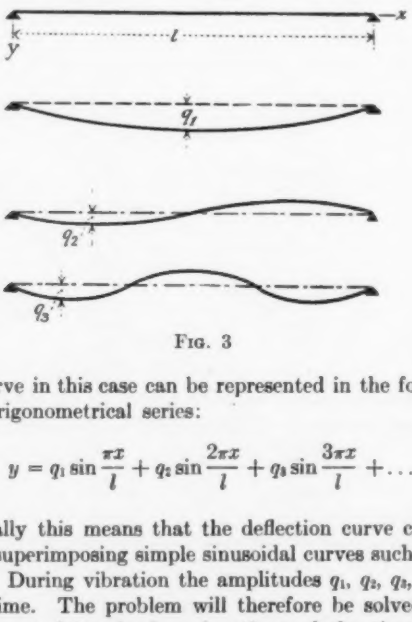

Fig. 3

flection curve in this case can be represented in the form of the following trigonometrical series:

$$y = q_1 \sin\frac{\pi x}{l} + q_2 \sin\frac{2\pi x}{l} + q_3 \sin\frac{3\pi x}{l} + \ldots\ldots [11]$$

Geometrically this means that the deflection curve can be obtained by superimposing simple sinusoidal curves such as shown in Fig. 3. During vibration the amplitudes $q_1, q_2, q_3, \ldots$ vary with the time. The problem will therefore be solved if these amplitudes are determined as functions of the time. In the following discussion of the problem we shall consider the quantities $q_1, q_2, q_3, \ldots$ as *generalized coordinates* of the vibrating beam and shall use general expressions for kinetic and potential energy expressed in terms of these quantities. The potential energy in this case will be the energy of bending, which can be calculated from the following known equation:

$$V = \frac{EI}{2}\int_0^l \left(\frac{d^2y}{dx^2}\right)^2 dx \ldots\ldots [12]$$

Substituting series [11] for $y$ in this equation and taking into consideration the fact that:

$$\int_0^l \sin\frac{m\pi x}{l}\sin\frac{n\pi x}{l}\,dx = 0 \text{ when } m \neq n$$

$$\int_0^l \sin^2\frac{m\pi x}{l}\,dx = \frac{l}{2}$$

we obtain

$$V = \frac{EI}{2}\left(\frac{\pi^4}{2l^3}q_1^2 + \frac{2^4\pi^4}{2l^3}q_2^2 + \frac{3^4\pi^4}{2l^3}q_3^2 + \ldots\right)$$

$$= \frac{EI\pi^4}{4l^3}\sum_{i=1}^{i=\infty} i^4 q_i^2 \ldots\ldots [13]$$

In calculating the kinetic energy of the vibrating beam the following symbols will be used:

$A$ = cross sectional area of the beam

$\gamma$ = weight of the material per unit volume.

Then the kinetic energy of one element $dx$ of the beam will be

$$\frac{A\gamma}{2g}\dot{y}^2\,dx$$

and the complete kinetic energy of the vibrating beam becomes:

$$T = \frac{A\gamma}{2g}\int_0^l \dot{y}^2\,dx \ldots\ldots [14]$$

Substituting series [11] for $y$ and taking into consideration that $q_1, q_2, \ldots$ are functions of the time, we obtain:

$$T = \frac{A\gamma}{2g}\int_0^l \left(\dot{q}_1 \sin\frac{\pi x}{l} + \dot{q}_2 \sin\frac{2\pi x}{l} + \dot{q}_3 \sin\frac{3\pi x}{l} + \ldots\right)^2 dx$$

or, after integration,

$$T = \frac{A\gamma}{2g}\left(\dot{q}_1^2\frac{l}{2} + \dot{q}_2^2\frac{l}{2} + \dot{q}_3^2\frac{l}{2} + \ldots\right) = \frac{A\gamma l}{4g}\sum_{i=1}^{i=\infty}\dot{q}_i^2 \ldots [15]$$

To obtain the quantities $q_1, q_2, q_3, \ldots$ we shall use now Lagrange's general equations of dynamics which have the following form:

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{q}_i} - \frac{\partial T}{\partial q_i} + \frac{\partial V}{\partial q_i} = Q_i \ldots\ldots [16]$$

In this equation $\frac{\partial T}{\partial q_i}$ and $\frac{\partial V}{\partial q_i}$ represent, respectively, the partial derivative of the kinetic energy with respect to any coordinate $q_i$ and the partial derivative with respect to the corresponding velocity $\dot{q}_i$. $Q_i$ represents the generalized disturbing force corresponding to the coordinate $q_i$. In order to find $Q_i$ in any particular case it is only necessary to give to the coordinate $q_i$ an infinitely small increase $\delta q_i$ and to calculate the work $\delta W$ produced by the external forces during the increase $\delta q_i$ of the coordinate $q_i$. $Q_i$ will thus be found from the equation

$$Q_i = \frac{\delta W}{\delta q_i} \ldots\ldots [17]$$

Several examples of the calculation of the generalized force $Q_i$ will be shown later.

Substituting the expressions for $T$ and $V$ in Equation [16] the following differential equation of motion will be obtained for each coordinate $q_i$:

$$\frac{A\gamma l}{2g}\ddot{q}_i + \frac{EI\pi^4 i^4}{2\,l^3} q_i = Q_i$$

or

$$\ddot{q}_i + \frac{a^2 i^4 \pi^4}{l^4} q_i = \frac{2g}{A\gamma l} Q_i \qquad [18]$$

in which

$$a^2 = \frac{EIg}{A\gamma} \qquad [19]$$

The differential equation [18] is a linear differential equation with constant coefficients which may easily be solved provided the force $Q_i$ is known as a function of time. The complete integral can then be represented in the following form:

$$q_i = A_i \cos\frac{i^2\pi^2 at}{l^2} + B_i \sin\frac{i^2\pi^2 at}{l^2} + \frac{l^2}{i^2\pi^2 a}\,\frac{2g}{\gamma Al}\int_0^t Q_i \sin\frac{i^2\pi^2 a}{l^2}(t - t_1)dt_1 \qquad [20]$$

The first two terms in this solution represent the free vibration determined by the initial conditions, while the third term represents the vibration produced by the disturbing force $Q_i$. The period of the natural vibration will thus be

$$T_i = \frac{2\pi l^2}{i^2\pi^2 a} = \frac{2\,l^2}{i^2\pi}\sqrt{\frac{A\gamma}{EIg}} \qquad [21]$$

and its frequency is therefore

$$f_i = \frac{1}{T_i} = \frac{i^2\pi}{2l^2}\sqrt{\frac{EIg}{A\gamma}} \qquad [22]$$

This natural vibration corresponds to the coordinate $q_i$. The corresponding deflection curve (Fig. 3) has $i$ waves and $i - 1$ nodes. It is seen that with increase of the number of waves $i$ the frequency increases as $i^2$. Vibrations produced by disturbing forces will now be considered.

### Pulsating Force

As an example let us consider first the case of a pulsating force $P = P_0 \sin nt_1$ applied at a distance $c$ from the left support (see Fig. 4) and having the period $2\pi/n$. In order to obtain a generalized force $Q_i$ in Equation [18] for this case let us assume that a small increase $\delta q_i$ is given to a coordinate $q_i$. The corresponding deflection of the beam, from [11], will be $\delta y = \delta q_i \sin\frac{i\pi x}{l}$, and the work done by the external force $P$ on this displacement is:

$$\delta W = P\delta q_i \sin\frac{i\pi c}{l}$$

Then from Equation [17]

$$Q_i = P\sin\frac{i\pi c}{l} = P_0 \sin\frac{i\pi c}{l}\sin nt_1 \qquad [23]$$

Substituting in Equation [20] and considering only the third term representing vibration produced by the pulsating force, we obtain:

$$q_i = \frac{2g}{\gamma A}P_0 \sin\frac{i\pi c}{l}\left[\frac{l^3}{i^4\pi^4 a^2 - n^2 l^4}\sin nt - \frac{nl^5}{i^2\pi^2 a(i^4\pi^4 a^2 - n^2 l^4)}\sin\frac{i^2\pi^2 at}{l^2}\right] \qquad [24]$$

Substituting in Equation [11], we have

$$y = \frac{2gP_0 l^3}{\gamma A}\sum_{i=1}^{i=\infty}\frac{\sin\frac{i\pi c}{l}\sin\frac{i\pi x}{l}}{i^4\pi^4 a^2 - n^2 l^4}\sin nt - \frac{2gn\,P_0 l^5}{\gamma A\pi^2 a}\sum_{i=1}^{i=\infty}\frac{\sin\frac{i\pi c}{l}\sin\frac{i\pi x}{l}}{i^2(i^4\pi^4 a^2 - n^2 l^4)}\sin\frac{i^2\pi^2 at}{l^2} \qquad [25]$$

It is seen that the first series in this solution is proportional to $\sin nt$. It has the same period as the disturbing force and represents forced vibrations of the beam. The second series represents free vibrations of the beam produced by the application of the force. The latter type of vibrations will be gradually

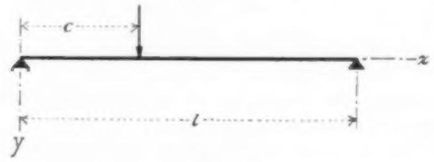

Fig. 4

damped out because of friction, internal hysteresis, etc. Hence, only the forced vibrations, given by the equation

$$y = \frac{2gP_0 l^3}{\gamma A}\sum_{i=1}^{i=\infty}\frac{\sin\frac{i\pi c}{l}\sin\frac{i\pi x}{l}}{i^4\pi^4 a^2 - n^2 l^4}\sin nt \qquad [26]$$

are of practical importance.

If the pulsating force $P$ is varying very slowly, $n$ is a very small quantity and $n^2 l^4$ can be neglected in the denominator of the series [26]. In such cases the expression for $y$ becomes:

$$y = \frac{2gPl^3}{\gamma A\pi^4 a^2}\sum_{i=1}^{i=\infty}\frac{1}{i^4}\sin\frac{i\pi c}{l}\sin\frac{i\pi x}{l} \qquad [27]$$

or, by using Equation [19],

$$y = \frac{2Pl^3}{EI\pi^4}\sum_{i=1}^{i=\infty}\frac{1}{i^4}\sin\frac{i\pi c}{l}\sin\frac{i\pi x}{l} \qquad [28]$$

This expression represents the statical deflection of the beam produced by the load $P$.[9] In the particular case, when the force $P$ is applied at the middle, $c = l/2$, and we obtain

$$y = \frac{2Pl^3}{EI\pi^4}\left(\sin\frac{\pi x}{l} - \frac{1}{3^4}\sin\frac{3\pi x}{l} + \frac{1}{5^4}\sin\frac{5\pi x}{l} + \ldots\right) \qquad [29]$$

This series converges rapidly, and a satisfactory approximation for the deflections will be obtained by taking the first term only. In this manner we find for the deflection at the middle,

$$\left(y\right)_{x = l/2} = \frac{2Pl^3}{EI\pi^4} = \frac{Pl^3}{48.7EI}$$

The error of this approximation is thus about 1.5 per cent. Denoting by $\alpha$ the ratio of the frequency $n/2\pi$ of the disturbing force to the frequency $a\pi/2l^2$ of the fundamental type of free vibration, we have:

$$\alpha = \frac{nl^2}{a\pi^2}$$

[9] See "Applied Elasticity," by S. Timoshenko and J. M. Lessells, p. 131.

and the series [26], representing the forced vibrations, becomes

$$y = \frac{2P_0\, l^3 \sin nt}{EI\pi^4} \sum_{i=1}^{i=\infty} \frac{\sin \frac{i\pi c}{l} \sin \frac{i\pi x}{l}}{i^4 - \alpha^2}$$

If the pulsating force is applied at the middle, we obtain

$$y = \frac{2P_0 \sin ntl^3}{EI\pi^4}\left[\frac{\sin \frac{\pi x}{l}}{1-\alpha^2} - \frac{\sin \frac{3\pi x}{l}}{3^4-\alpha^2} + \frac{\sin \frac{5\pi x}{l}}{5^4-\alpha^2} + \ldots\right] \ldots [30]$$

For small values of $\alpha$ the first term of this series represents the deflection with good accuracy. By comparing [30] with [29] it can be concluded that the ratio of the dynamical deflection to the statical deflection is approximately equal to

$$\frac{1}{1-\alpha^2} \ldots\ldots\ldots\ldots [31]$$

If, for instance, the frequency of the disturbing force is one-fourth that of the fundamental mode of vibration, the dynamical deflection will be about 6 per cent greater than the statical deflection.

Since problems involving small vibrations of beams are represented by *linear* differential equations, the principle of superposition holds. Hence, if we have several pulsating forces acting on the beam the resulting vibration will be obtained by superimposing the vibration produced by the individual forces. The case of continuously distributed pulsating forces also can be solved in the same manner; the summation has only to be replaced by an integration along the length of the beam. Assume, for instance, that the beam is loaded by a uniformly distributed pulsating load of the intensity

$$q = q_0 \sin nt$$

Such a condition of loading will exist, for instance, in a locomotive side rod due to the action of variable bending inertia forces. In order to solve this case, $q_0 dc$ should be substituted for $P_0$ in Equation [26] and the integration carried out with respect to $c$, the limits being $c = 0$ and $c = l$. In this manner, there is obtained:

$$y = \frac{4gq_0 l^4}{\gamma A\pi} \sum_{i=1,3,5\ldots}^{i=\infty} \frac{\sin \frac{i\pi x}{l} \sin nt}{i(i^4\pi^4 a^2 - n^2 l^4)} \ldots\ldots\ldots [32]$$

If the frequency of the load is very small in comparison with the frequency of the fundamental mode of vibration of the bar, we may, as before, neglect term $n^2l^4$ in the denominators of the series [32]. The equation then becomes

$$y = \frac{4ql^4}{EI\pi^5}\left[\frac{\sin \frac{\pi x}{l}}{1^5} + \frac{\sin \frac{3\pi x}{l}}{3^5} + \frac{\sin \frac{5\pi x}{l}}{5^5} + \ldots\right] \ldots [33]$$

This very rapidly converging series represents the statical deflection of the beam produced by a uniformly distributed load $q$. By taking $x = l/2$ we obtain for the deflection at the middle

$$\left(y\right)_{x=l/2} = \frac{4ql^4}{EI\pi^4}\left[1 - \frac{1}{3^5} + \frac{1}{5^5} + \ldots\right] \ldots\ldots [34]$$

If only the first term of this series be used, the error in calculating the deflection at the middle will be about $1/_4$ per cent. If the frequency of the pulsating load is not small enough to warrant the application of the statical equation, the method used in the case of a single force can be used and we shall arrive at the same conclusion as represented by Equation [31]

### Moving Constant Force

If a constant vertical force $P$ is moving along the length of a beam it produces vibrations which can be calculated without any difficulty by using the general Equation [20]. Let $v$ denote the constant velocity of the moving force and let the force be at the left support at the initial moment ($t = 0$); then at any other moment the distance of this force from this left support will be $vt_1$. In order to determine the generalized force $Q_i$ for this case, assume that the coordinate $q_i$ in the general expression [11] of the deflection curve obtains an infinitely small increase $\delta q_i$. The work done by the force $P$ due to this displacement will be

$$P\left(\delta y\right)_{x=vt_1} = P\delta q_i \sin \frac{i\pi v t_1}{l}$$

Hence, the generalized force

$$Q_i = P \sin \frac{i\pi v t_1}{l}$$

Substituting this in the third term of Equation [20], the following expression will be found for the vibration produced by the moving load:[10]

$$y = \frac{2gPl^3}{\gamma A\pi^2} \sum_{i=1}^{i=\infty} \frac{\sin \frac{i\pi x}{l}}{i^2(i^2\pi^2a^2 - v^2l^2)} \sin \frac{i\pi vt}{l}$$

$$- \frac{2gPl^4 v}{\gamma A\pi^3 a} \sum_{i=1}^{i=\infty} \frac{\sin \frac{i\pi x}{l}}{i^3(i^2\pi^2a^2 - v^2l^2)} \sin \frac{i^2\pi^2 at}{l^2} \ldots\ldots [35]$$

The first series in this solution represents the forced vibrations, and the second series the free vibrations of the beam.

If the velocity $v$ of the moving force be very small, we can put $v = 0$ and $vt = c$ in the solution above; then

$$y = \frac{2gPl^3}{\gamma A\pi^4 a^2} \sum_{i=1}^{i=\infty} \frac{1}{i^4} \sin \frac{i\pi c}{l} \sin \frac{i\pi x}{l}$$

This is the statical deflection of the beam produced by the load $P$ applied at a distance $c$ from the left support—see Equation [27]. By using the notation

$$\alpha^2 = \frac{v^2l^2}{a^2\pi^2} \ldots\ldots\ldots\ldots [36]$$

the part of the general solution [35] representing forced vibrations becomes

$$y = \frac{2Pl^3}{EI\pi^4} \sum_{i=1}^{i=\infty} \frac{\sin \frac{i\pi x}{l} \sin \frac{i\pi vt}{l}}{i^2(i^2 - \alpha^2)} \ldots\ldots\ldots [37]$$

It is interesting to note that the expression for this deflection is identical with that for the statical deflection of a beam[11] on which, in addition to the lateral load $P$ applied at a distance $c = vt$ from the left support, a longitudinal compressive force $S$ is acting,

[10] This problem is of practical interest in connection with the study of bridge vibrations. The first solution was obtained by A. N. Kriloff, member of the Academy of Sciences in St. Petersburg; see *Mathematische Annalen*, vol. 61 (1905), and also the author's paper in the "Bulletin of the Polytechnical Institute in Kiew" (1908), German translation in *Zeit. f. Math. u. Phys.*, vol. 59 (1911). Prof. C. E. Inglis in the Proc. of the Inst. of Civil Engineers, vol. 218 (1924), London, came to the same results.

[11] See "Applied Elasticity" mentioned above, p. 163. By using the known expression for the statical deflection curve, the finite form of the function, from which the series [37] has its origin, can be obtained.

the value of $S$ being such that

$$S : S_{cr} = \frac{Sl^2}{EI\pi^2} = \alpha^2 \ldots\ldots\ldots\ldots\ldots [38]$$

Here $S_{cr}$ denotes the known critical load which will cause buckling of the beam. From Equations [37] and [38] we obtain

$$\frac{Sl^2}{EI\pi^2} = \frac{v^2l^2}{a^2\pi^2}$$

or

$$S = \frac{v^2A\gamma}{g} \ldots\ldots\ldots\ldots\ldots\ldots [39]$$

The effect of this force $S$ on the statical deflection of the beam loaded by the force $P$ is therefore equivalent to the effect of the velocity of the moving force $P$ on the deflection produced as a consequence of forced vibrations.

By increasing the velocity $v$ a condition can be reached where one of the denominators in the series [35] becomes equal to zero and hence resonance takes place. Assume, for instance, that

$$a^2\pi^2 = v^2l^2 \ldots\ldots\ldots\ldots\ldots\ldots [40]$$

In this case the period of the fundamental mode of vibration of the beam, equal to $\frac{2l^2}{a\pi}$, becomes equal to $\frac{2l}{v}$, and hence is twice as great as the time required for the force $P$ to pass over the beam. The denominators in the first terms of both series in Equation [35] become, under the condition [40], equal to zero, and the sum of these two terms will be

$$\frac{2gPl^3}{\gamma A\pi^2} \sin\frac{\pi x}{l} \frac{\sin\frac{\pi vt}{l} - \frac{lv}{\pi a}\sin\frac{\pi^2 at}{l^2}}{\pi^2a^2 - v^2l^2}$$

This expression has the form $\frac{0}{0}$ and may be evaluated in the usual way. It then takes the following form:

$$-\frac{Pgt}{\gamma A\pi v}\cos\frac{\pi vt}{l}\sin\frac{\pi x}{l} + \frac{Pgl}{\gamma A\pi^2v^2}\sin\frac{\pi vt}{l}\sin\frac{\pi x}{l} \ldots [41$$

Expression [41] has its maximum value when

$$t = \frac{l}{v}$$

and is then equal to

$$+\frac{Pgl}{\gamma A\pi^2v^2}\left[\sin\frac{\pi vt}{l} - \frac{\pi vt}{l}\cos\frac{\pi vt}{l}\right]_{t=\frac{l}{v}} \sin\frac{\pi x}{l} = \frac{Pl^3}{EI\pi^3}\sin\frac{\pi x}{l} \ldots [42]$$

Taking into consideration the fact that the expression [41] represents a satisfactory approximation for the dynamical deflection given by Equation [35], it can be concluded that the maximum dynamical deflection at the resonance condition, i.e., when Equation [40] is satisfied, is about 50 per cent larger than the maximum statical deflection, which is equal to $\frac{Pl^3}{48\,EI}$. It is interesting to note that the maximum dynamical deflection occurs when the force $P$ is leaving the beam. At this moment the deflection under the force $P$ is equal to zero, hence the net work done by this force when it has just passed the length of the beam is equal to zero. In order to explain the source of the energy accumulated in the vibrating beam during the passing over of the force $P$ we should assume that there is no friction and the beam produces a reaction $R$ in the direction of the normal (Fig. 5). In this case, from the condition of equilibrium it follows that there should exist a horizontal force, equal to $P\frac{dy}{dx}$. The work done by this force during its passage along the beam will be

$$W = -\int_0^{l/v} P\left(\frac{dy}{dx}\right)_{x=vt} v\,dt$$

Substituting expression [41] for $y$ we obtain

$$W = -\frac{P^2g}{\gamma A\pi v^2}\int_0^{l/v}\left(\sin\frac{\pi vt}{l} - \frac{\pi vt}{l}\cos\frac{\pi vt}{l}\right)\cos\frac{\pi vt}{l}\,v\,dt$$
$$= \frac{P^2gl}{\gamma A\pi^2v^2} \times \frac{\pi^2}{4}$$

or, by taking into consideration the relations given by Equations [40] and [19], we obtain a value for the work done equal to:

$$W = \frac{\pi^2}{4}\frac{P^2l^3}{EI\pi^4}$$

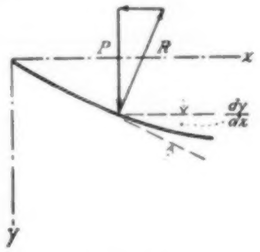

Fig. 5

This amount of work is approximately equal[12] to the amount of the potential energy of bending of the beam at the moment $t = l/v$. In the case of bridges the time necessary to cross the bridge is usually large in comparison with the period of the fundamental type of vibration; hence the quantity $\alpha^2$, given by Equation [9] is small. Then by taking only the first term in each series of Equation [35] and assuming that in the most unfavorable case the amplitudes of the forced and free vibration are added directly, we obtain for the maximum deflection

$$y_{max.} = \frac{2gPl^3}{\gamma A\pi^2}\left(\frac{1}{\pi^2a^2 - v^2l^2} + \frac{vl}{a\pi}\frac{1}{\pi^2a^2 - v^2l^2}\right)$$
$$= \frac{2Pl^3}{EI\pi^4}\frac{1+\alpha}{1-\alpha^2} = \frac{2Pl^3}{EI\pi^4}\frac{1}{1-\alpha} \ldots\ldots\ldots [43]$$

This is a somewhat exaggerated value of the maximum dynamical deflection, because damping has been neglected in the above discussion.

By using the principle of superposition the solution of the problem in the case of a system of concentrated moving forces and in the case of moving distributed forces can be also solved without difficulty.[13]

## Moving Pulsating Force

Consider now the case when a pulsating force is moving along the beam with a constant velocity $v$ (Fig. 6). Such a condition may exist, for instance, when an imperfectly balanced locomotive passes over a bridge. The vertical component of the centrifugal force $P$, due to the unbalance, is

$$P\cos\omega t_1$$

where $\omega$ = the angular velocity of the driving wheel.

By using the same manner of reasoning as before, the following expression for the generalized force, corresponding to the generalized coordinate $q_i$ will be obtained:

[12] The potential energy of a beam bent by a force $P$ at the middle is $V = \frac{P^2l^3}{96\,EI}$ and $\frac{W}{V} = 2.43$. This ratio is very close to the square of the ratio of the maximum deflection for dynamical and statical conditions, which is equal to $\left(\frac{48}{\pi^3}\right)^2 = 2.38$. The discrepancy may be attributed to the higher harmonics in the deflection curve.

[13] See author's paper mentioned in footnote No. 10.

$$Q_i = P \cos \omega t_1 \sin \frac{i\pi v t_1}{l}$$

Substituting this in the third term of the general solution [20] we obtain

$$y = \frac{Pl^3}{EI\pi^4} \sum_{i=1}^{i=\infty} \sin \frac{i\pi x}{l} \left\{ \frac{\sin\left(\frac{i\pi v}{l} + \omega\right)t}{i^4 - (\beta + i\alpha)^2} + \frac{\sin\left(\frac{i\pi v}{l} - \omega\right)t}{i^4 - (\beta - i\alpha)^2} \right.$$

$$\left. - \frac{\alpha}{i}\left[ \frac{\sin \frac{i^2\pi^2 at}{l^2}}{-i^2\alpha^2 + (i^2 - \beta)^2} + \frac{\sin \frac{i^2\pi^2 at}{l^2}}{-i^2\alpha^2 + (i^2 + \beta)^2} \right] \right\} \quad .. [44]$$

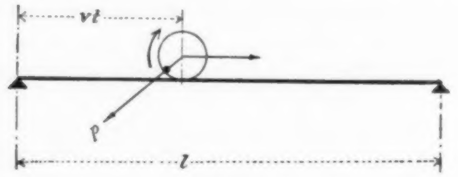

FIG. 6

where $\alpha = \frac{vl}{a\pi}$ = the ratio of the period $T = \frac{2l^2}{\pi a}$ of the fundamental type of vibration of the beam to twice the value of the time $T_1 = \frac{l}{v}$ necessary for the force $P$ to pass over the beam.

$\beta = \frac{T}{T_2}$ = the ratio of the period of the fundamental type of vibration of the beam to the period $T_2 = \frac{2\pi}{\omega}$ of the pulsating force. When the period $T_2$ of the pulsating force is equal to the period $T$ of the fundamental type of vibration of the beam $\beta = 1$ and we obtain a condition of resonance, the amplitude of vibration during motion of the pulsating force will be gradually built up and will attain its maximum at the moment $T = \frac{l}{v}$. At this instant the first term (for $i = 1$) in the series of the right-hand member of [44], which is the most important part of $y$, may be reduced to the form

$$\frac{1}{\alpha} \frac{2Pl^3}{EI\pi^4} \sin \frac{\pi x}{l} \sin \omega t$$

The maximum deflection is thus given approximately by the formula

$$\delta_{\max.} = \frac{1}{\alpha}\frac{2Pl^3}{EI\pi^4} = \frac{2T_1}{T}\frac{2Pl^3}{EI\pi^4} \quad \ldots\ldots\ldots\ldots [45]$$

Owing to the fact that in actual cases the time interval $T_1 = \frac{l}{v}$ is large in comparison with the period $T$ of the natural vibration, the maximum dynamical deflection produced by the pulsating force $P$ will be many times the deflection $\frac{2Pl^3}{EI\pi^4}$ which would be produced by the same force applied statically at the middle of the beam.

In the case of bridges having short spans, where the natural frequency of vibration is considerably higher than the number of revolutions per second of the driving wheels, a satisfactory approximation can be obtained by taking only the first term of the solution [44] and assuming the most unfavorable condition, namely, that at the moment $t = \frac{l}{2v}$ when the pulsating force arrives at the middle of the span, $\sin\left(\frac{\pi v}{l} + \omega\right)t$ and $\sin\left(\frac{\pi v}{l} - \omega\right)t$ become equal to 1 and $\sin \frac{\pi^2 at}{l^2}$ becomes equal to $-1$. Then the additional deflection, from [44], will be

$$\delta = \frac{Pl^3}{EI\pi^4}\left\{ \frac{1}{1 - (\beta + \alpha)^2} + \frac{1}{1 - (\beta - \alpha)^2} + \frac{\alpha}{(1 - \beta)^2 - \alpha^2} + \frac{\alpha}{(1 + \beta)^2 - \alpha^2} \right\}$$

$$= \frac{2Pl^3}{EI\pi^4}\left\{ \frac{1 - \alpha}{\left[1 - \beta\left(1 + \frac{\alpha}{\beta}\right)\right]\left[1 + \beta\left(1 - \frac{\alpha}{\beta}\right)\right]} \right\} \quad \ldots. [46]$$

The application of this equation is shown in the paper proper.

## Discussion

A. I. LIPETZ.[14] The writer has been interested in locomotive counterbalances for a long time, chiefly from the standpoint of effect of the excess counterbalance on rails, and has found in comparing actual stress records obtained from special recording apparatus that the difference between the steam and electric locomotive is not so high as one might expect. The electric locomotive is supposed to be perfectly balanced, and it should not have this additional impact effect on bridges which Professor Timoshenko mentions. In comparing the recorded figures it is difficult to account for the small difference, for in heavy locomotives counterbalances sometimes have very considerable excess balances. It is possible that the time element has an effect. Perhaps Professor Timoshenko will explain whether or not the dynamic force, if its translation and time element are taken into consideration, would total all our results so as to make the dynamic effect negligible.

At high speeds the excess counterbalance may give a theoretically larger dynamic augment, but the time of its action is shorter and the section of highest stress travels more rapidly. In other words, it is possible that the higher the speed of the locomotive the lesser the effect relatively, and this may explain why locomotives with very heavy excess counterbalances are running safely and cause few rail breakages, whereas a slight increase in static weight per axle seems to cause breakages.

GEORGE E. THACKRAY.[15] Having been interested in rails for many years, the writer has had occasion at various times to notice the effects of unbalanced drivers on railway roadbeds. There have been many examples in this country of medium- and heavy-weight rails being deflected and bent at distances apart about equal to the circumference of a locomotive driving wheel, due to the action of the unbalanced moving parts.

It is impossible to balance a locomotive driver perfectly, because of the combined unbalancing effects of the reciprocating and revolving connecting rods, the revolving side rods, and the horizontally reciprocating piston, piston rod, and crosshead, as these parts have differing motions, all of which cannot be counterbalanced by the usual revolving weights on the driving wheels.

Referring now to the remarks of Mr. Lipetz regarding the damping of the vibrations of a bridge, it seems that the vibration of a bridge as a whole, to a certain extent, determines some of the stresses which would be found in some of its members. How-

[14] Consulting Engineer, American Locomotive Co., Schenectady, N. Y. Mem. A.S.M.E.

[15] Special Engineer, Bethlehem Steel Co., Bethlehem, Pa. Mem. A.S.M.E.

ever, in bridges of long spans on which one train load is two heavy locomotives followed by 6000 lb. per ft. or more, the inertia of the load of the train itself would cause a very appreciable dampening upon the vibration of the bridge as a whole.

The greatest effect of such a moving load, with respect to vibration and impact, would be upon the members which are directly under or near the rails, such as the floor beams and stringers, and much less upon a long and heavy bridge as a whole.

G. M. Eaton.[16] Since the dynamic augment comes first on one side of the locomotive and then on the other, there must be a turning tendency introduced, and the bridge being weaker laterally and torsionally than it is vertically, there would seem to be danger from this source. Perhaps Professor Timoshenko will go into this matter in his closure.

H. W. Fitch.[17] Observations in the shops show that frequently there are engines which are so far out of proper balance that it seems quite possible to produce the effects which Mr. Thackray has spoken of; that is, permanent deformation of the rails at intervals equal to the circumference of the driver. There seems to be a practical problem there for the railroads in properly maintaining engines which have been correctly counterbalanced upon leaving the builders.

William Elmer.[18] The comments of Mr. Fitch recall an experience when the writer was master mechanic at one of our shops. A certain locomotive came in for its general repairs, and upon examining the main drivers on the left side it was found that there was no counterbalance whatever. Lead had been poured into the space provided, but unfortunately the plugs which closed the holes had worked out, allowing the weights to become loose inside the retaining casing. The lead then had, apparently, due to the countless revolutions of the wheel, become completely disintegrated and worked out of the holes. The locomotive had been running back and forth over the road with absolutely no counterbalance whatever on the driving wheel.

During our tests at the St. Louis Exposition, it was the practice to run a wire underneath the main driver in order to get some indication of the counterbalance performance. It was found that some of the engines on the test plant when they were up to speed showed no weight whatever on the driving wheels at the point where the dynamic augment was at a minimum. Of course, at the opposite point of the revolution there was a marked flattening of the wire, indicating a very high increase in the dynamic augment.

The Author. Referring to the remarks of Mr. Lipetz, the author would state that the period of free vibration of a rail as a bar on an elastic foundation is very short in comparison with the time of one revolution of the locomotive wheel. Under such conditions the stresses and deflections produced by counterbalance weights will be nearly the same as those calculated from statical considerations. It is also an established fact that the *endurance limit* of steel under reversal of stresses is the same for 200 and for 2000 cycles per minute. An increase in endurance limit becomes noticeable only at very high frequency, such as 30,000 cycles per minute.

In comparing the stresses produced by static weights with those due to excess counterbalances, it is necessary to keep in mind that static weights produce deflections convex downward under the wheel and convex upward in the interval between two wheels, so that in each individual cross-section of the rail the stresses produced by static weights are reversed several times during one passage of the locomotive. The counterbalance weights produce additional stress in certain fixed sections of the rail, the distance between which is equal to the circumference of the wheel. In consecutive rides these overstressed sections will not coincide, hence the effect of such additional stress on fatigue of steel will be less than that produced by static weights.

Referring to the remark of Mr. Eaton, the author would state that the method developed in the paper can be used also in investigating lateral vibrations of bridges. These vibrations may be of great practical importance, the bridges usually being weaker laterally and torsionally than they are vertically.

Mr. Thackray, in his discussion, makes a remark on the appreciable dampening effect which is produced on the vibration of the bridge by the inertia of the weight of the train. Such a dampening effect is an established fact. It has been proved by experiments of the Indian Railway Bridge Committee mentioned in the paper.

# Electric Interlocking System

## Installation by the Boston & Albany Railroad at Its New Station in Springfield, Mass., Centralizes Control of All Switches and Signals

By R. J. Cullen,[1] Boston, Mass.

Coincident with the construction of a new and modern station at Springfield, Mass., which included a rearrangement of tracks to provide adequate and efficient operation for handling the ever-increasing freight and passenger traffic at this point, an electric interlocking system was installed by the Boston & Albany Railroad which centralized the control of all switches and signals at the east and west ends of the station in one plant.

The safe, expeditious, and economical handling of railway traffic at junctions and terminals on the vast railway systems of the country led to the development of interlocking plants that provide a dependable method of operating switches and signals from a central point under the control of levers in an interlocking machine. Traffic thus controlled is not only greatly expedited, but train operation, even when conducted under the most intense operating conditions, is handled with an increased factor of safety.

An interlocking plant is an assemblage of switches, signals, and other appliances operated from the levers of an interlocking machine. An interlocking machine is an arrangement of switch and signal levers in a frame so interlocked that their movements must succeed each other in a predetermined order.

The features of vital importance in any system of electric interlocking are those that are designed to give the greatest measure of safety together with facility of operation. The features most important to safety are:

1 The means provided to insure coordination between the controlling levers in the interlocking machine.

2 The means provided to insure coordination between the levers and the switches, signals, or other functions controlled by them.

3 The means provided for preventing unauthorized movement of switches, signals, or other controlled functions.

4 The means provided for preventing the operation of the controlling levers except when it is safe and proper to do so.

The feature most important to provide facility of operation is the means to inform the operator at the signal station as to what is taking place on the roadway.

### Interlocking Machine

The interlocking machine, which is placed in the operating room of the signal station (Fig. 1) 45 ft. above the track level, consists of a 248-lever frame, with 185 working levers controlling 77 signals, 33 single switches, 17 movable point frogs, 34 double slip switches, 1 check lock lever, and 1 derail. An interlocking machine is shown in Fig. 2.

The levers, which are of the pistol-grip type, equipped with all necessary controllers and connections, are in a common frame. One lever is provided for the operation of each switch and signal. To operate the two switches of a crossover, two levers, one of which is equipped with all connections and the other minus hand grip, are fastened by a rigid connection to operate as one lever. With this arrangement the two ends of a crossover are operated simultaneously in the same length of time as is required to operate a single switch.

In explanation of the detail operation of a switch lever its movement can be considered as being divided into three parts, the preliminary, intermediate, and final. The preliminary and intermediate parts, however, usually constitute one continuous movement. In the preliminary movement of the lever the locking tappet is moved through one-half of its stroke, this movement locking all levers which conflict with the new position of the lever in question; in this movement no change whatsoever is made in the operating circuits. During the intermediate part of the travel the tappet bar remains stationary and the circuits for the operation of the function are set up. The lever is held at this point through the mechanical design of the lever proper, until such time as the function has moved to a corresponding position, which effects the release of the lever and permits its final movement. During this final movement the stroke of the locking tappet is completed, thereby unlocking all levers which do not conflict with the new position of the operated lever. The movement of the lever from reverse to normal is performed in a similar manner to that described.

The movement of the signal lever is identical with that of the switch lever except that it is not necessary to check the final position of the lever during reverse movement with the position of its controlled function.

The first important safety feature, that of insuring coordination between the controlling levers of the interlocking machine, is accomplished through the design of the machine so that no lever can be moved from a given position if any other lever that is mechanically interlocked therewith is in such a position that its controlled function will conflict with the function to be moved; and further, the mechanical locking is so constructed that the operation of a given lever from its position locks all conflicting levers against movement until such time as it is proper for them to be released. This feature is accomplished by the mechanical locking which is inserted between the controlling levers.

The mechanical locking insures that before a signal can be given for any route all switch and derail functions in the route are thrown to the proper positions and locked in that position and all opposing signals are in the stop position. No changes can be made in the position of any of these functions until the lever controlling the signal displayed at proceed has been replaced to its full normal position. This locking mechanism is mounted on locking plates securely attached to the front of the machine frame. The plates are designed with vertical and horizontal slots. The locking tappets, one of which is attached to each lever, are fitted each in the vertical slot directly beneath its respective lever. Movement is transmitted from the lever through the medium of the tappets to the cross-locking which slides back and forth in the horizontal slots of the locking plate.

The second important safety feature insuring coordination between the levers and the switches controlled by them is secured by means of dynamic-current indication, energy for which is furnished by a momentary dynamic current generated by the switch motor of the operated function itself when, and only when, the actual operation of such function shall have been properly completed. The use of the dynamic current generated by the mo-

mentum of the motor of the operated unit at one end of the circuit, and so giving the desired indication at the lever at the other end of the circuit, prevents the receipt of a false indication due to a cross between the wires of the circuit. As previously mentioned, no electrical indication is required during the reverse movement of a signal lever. However, in order to insure that the stop indication of a signal is displayed before the lever can be restored to its full normal position an indication must be obtained. This is secured by means of battery current controlled through a relay which directly repeats the stop indication of the signal.

The third essential safety feature, that of preventing unauthorized movements of controlled functions due to current being im-

Fig. 1 Station Tracks at West End of Layout, With Signal Station at Left, Three Top Floors

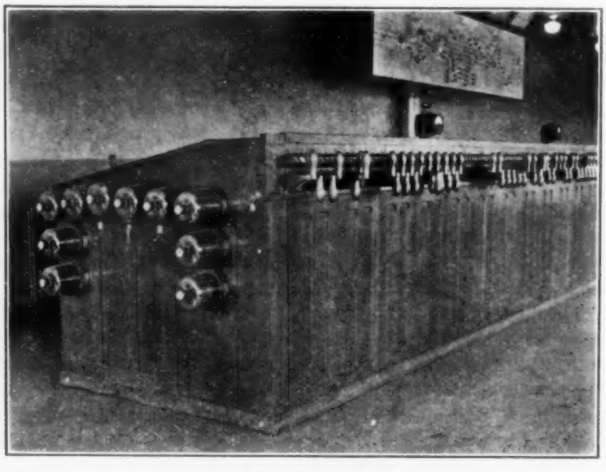

Fig. 2 Interlocking Machine

properly applied to its circuit by means of crosses or grounds, is accomplished as follows:

Each switch lever is equipped with a system known as individual cross-protection.

All switches while at rest are normally on a closed circuit of low resistance. A polarized relay of low resistance is inserted in each circuit and is mounted on the terminal board of the interlocking machine, the relay being connected in such a way that normal currents through the circuit due to manipulation of the lever flow through the relay in a direction to maintain its contact closed. However, currents improperly applied from crosses with other circuits or grounds must pass through this relay in a direction to cause its contact to open. The opening of this contact cuts off the negative energy for the switch, thereby preventing the unauthorized movement of the function. The windings of the polarized relay are so designed that its contact will open on about one-half the operating current.

The cross-protection system is installed on the closed-circuit principle, and all contacts and connections relied upon for protection are also used in operating the function, thereby securing complete check as to their integrity with every complete operation of the switch.

The unauthorized proceed indication of any signal is prevented by the placing of a shunt across the signal-operating wires by means of contacts actuated by the lever and closed only with the lever in the normal or stop position.

The fourth requisite necessary for safe operation consists of electric locking devices to guard against the possibility of a switch being operated under a train or in advance of an approaching train which has accepted a signal to proceed through the interlocking. This system of protection is known as sectional locking, sectional route locking, and approach locking. Each switch lever is equipped with a forced dropped electric lock. The coil of the lock is wound for direct-current operation at 12 volts. The lock is designed to be mounted on the top of the lever guide, locking the lever in the normal and reverse positions by means of a solenoid plunger, which, when the lock is de-energized, is forced into a notch cut on the top of the lever slide. The circuit controlling the lock coil is broken through various control relays that open or close depending upon whether one or several of the various track sections are occupied. By this means the switch levers controlling functions in any given section of track are locked in a definite position and cannot be operated by the leverman. This is called sectional locking. Sectional route locking as its name implies, is an extension or further development of

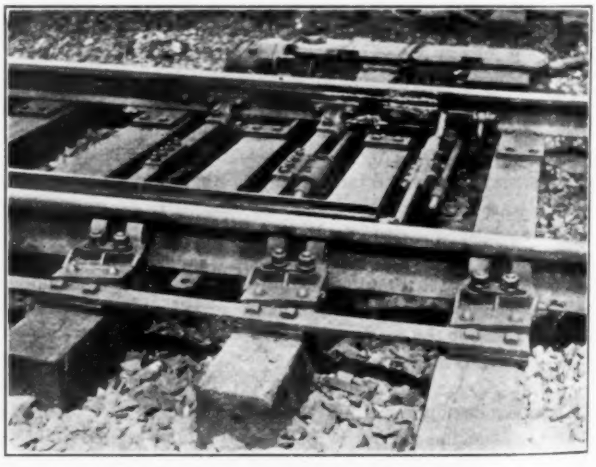

Fig. 3 Power-Operated Switch

sectional locking and route locking that, through the medium of track circuits and various control relays, locks all levers controlling switches in any route when the train passes the signal governing movements over that route. The approach locking will be explained in connection with the description of the signals.

### Switches

Each switch, movable-point frog, double slip switch, and derail is operated by a switch machine, which is a self-contained mechanism consisting of a motor, gearing, operating and locking members, pole changer, and a point detector of the over-and-locked type. Fig. 3 shows a power-operated switch.

The switch machines used (Fig. 4) are under the control of a lever in the interlocking machine and are operated by direct current at 110 volts. Machines are securely bolted to two ties and are usually placed approximately 3 feet from the gage of the nearest rail to the center line of the machine. Switch machines are rigidly maintained in their proper relation to the rail by the use of tie plates.

When the switch, in normal position, is to be operated, the first movement of the stroke of the controlling lever carries it as far as the reverse-indication position and permits current to flow, which causes the mechanism to move the switch points to the reverse position and to lock them in that position. When this movement has been completed, the circuit through the switch motor is automatically changed, disconnecting the motor from the battery and connecting it in a closed circuit including the indication magnet on the lever; at the same time the armature terminals are reversed for indication purposes, thus leaving the motor connections in proper position for the next operation. The motor, now a generator, with the momentum acquired during the operation of the switch movement generates a momentary current that energizes the indication magnet on the lever, thus permitting the final movement of the lever to be completed. The operation of the lever and function from the reverse to the normal position is accomplished in the same manner.

The complete switch operation with the final movement of the lever is accomplished in from 2 to $2^1/_2$ seconds, the indication being practically instantaneous with the completion of the switch operation.

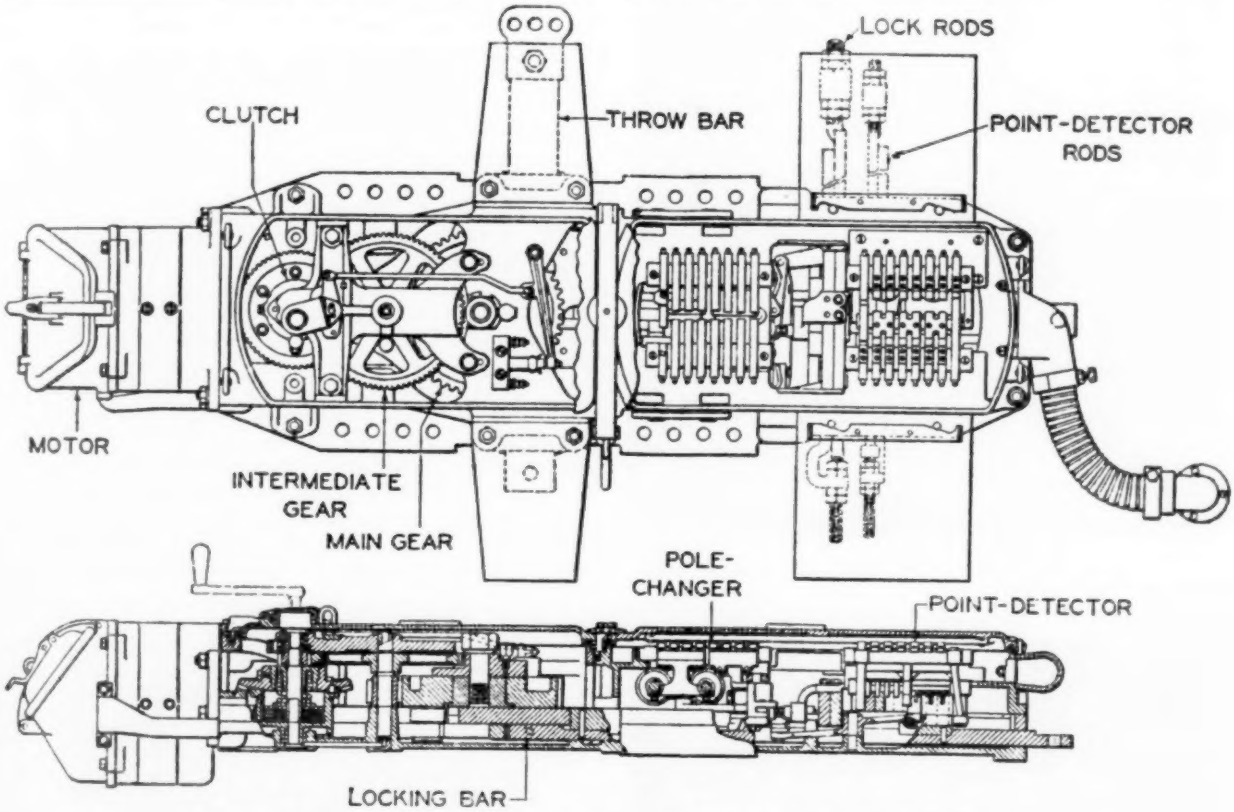

Fig. 4 Assembly of General Railway & Signal Company's Model 5A Switch Machine

### Signals

The signals are of the two- and three-indication color-light type displaying a light for both day and night indication, red being used for "Stop," yellow for "Proceed at slow speed prepared to stop," and green for "Proceed at restricted speed prepared to stop at the next signal." A three-indication color-light signal is shown in Fig. 5. Each signal is under the control of a lever in the interlocking machine and also is controlled through the switch-point detector mechanism of the switch machines in the particular route involved, thereby assuring that a proceed indication cannot be given to a train unless the switch points are in proper position and locked. The signals are equipped with the doublet-lens light units and are lighted by lamps rated at 10 volts and 20 watts. The approximate range of signals so equipped is 4000 to 5000 feet. Range is understood to mean the distance on a tangent, in bright sunlight, at which the indications are clear and distinct to a person of average eyesight. The design and the construction of this doublet-lens unit are such as to eliminate the possibility of phantom indication except those of so weak a nature as to be negligible.

Each signal controlling traffic for through movements is provided with a complete system of approach locking that prevents the changing of any switches in a given route for which the signal has been cleared for an approaching train. Should it be necessary, however, to change any route for which the proceed signal has been displayed, the approach locking may be released only after the stop indication has been displayed through the medium of clockwork time releases that can be adjusted for any time interval up to 5 minutes. This time interval is set to meet local speed conditions and to prevent the manipulation of levers that would endanger the train.

All signals not provided with approach locking are equipped with electric time-release contactors so arranged as to prevent the lever being restored to the full normal position until 10 seconds has elapsed after the signal has displayed the stop indication.

This arrangement guards against the possibility of the operator putting the signal at stop just as an engineman is passing it and changing switches in the route set-up before the track relay has opened and applied the electric locking.

### Track Circuits

The track circuit is the vital and fundamental feature of modern signaling. Upon the integrity of the track circuit rests

Fig. 5 Three-Indication Color-Light Signal

Fig. 6 West End of Track Layout Looking West From Signal Station

the proper and safe operation of the interlocking system. Its essential feature is a section of track insulated at each end from the adjoining sections of track. Each rail in this section is connected to the ones adjoining by bond wires, for the purpose of making a continuous conductor from one end of the section to the other. At one end of the insulated track section current is fed to the rail from a small transformer. Each transformer has a capacity of 75 volt-amperes with 110-volt primary and 12-volt secondary, having adjustable taps in steps of 1 volt. At the other end of the section a polyphase two-position track relay is connected to the rails. We now have a continuous closed circuit from the transformer through the rails of the track section to the relay. The presence of a pair of wheels or of a train in the section will short-circuit the transformer, shunting the current from the relay and causing it to assume the de-energized or open position. Consequently the relay is deprived by the wheels and axles of the current necessary to maintain its closed position. The track relay is equipped with the necessary contact points through which are controlled the various secondary relays for operation of the interlocking system.

The track layout at Springfield is divided into 58 separate track sections arranged to secure the necessary measure of safety combined with the maximum flexibility of operation. Parts of the track layout are shown in Figs. 6 and 7. Flexible operation of any system of interlocking depends largely upon the rapidity of operation of the individual functions and its capabilities for permitting simultaneous operation of a number of functions.

### Track and Signal Indicator

It has been stated elsewhere in this paper that the feature most important for facilitating operation in a plant of this kind is the means provided to inform the operator as to what is taking place on the roadway. This feature is provided through the medium of an illuminated track and signal indicator. The indicator, which also serves as a diagram for the numbered functions, is mounted on a steel frame suspended from the ceiling of the operating room directly over the interlocking machine (Fig. 8). This indicator is a miniature track layout showing all the track sections, switches, and signals in their respective locations. The track circuit blocks are illuminated with white electric lamps when the track section is clear, and the lamps go out automatically when the track section is occupied. For repeating the indication displayed by the signals small electric lamps are also used. These lamps are arranged to be illuminated red when the signal displays a stop indication and to show green when a proceed indication is displayed. With this arrangement a lamp failure in the track-circuit section will indicate to the operator that the section is occupied, and whether or not such indication is correct, safe operation is assured. The lamps for illuminating the indicator are supplied with current from a transformer connected to the main power supply and are directly controlled from the various track circuit sections and signal repeating relays.

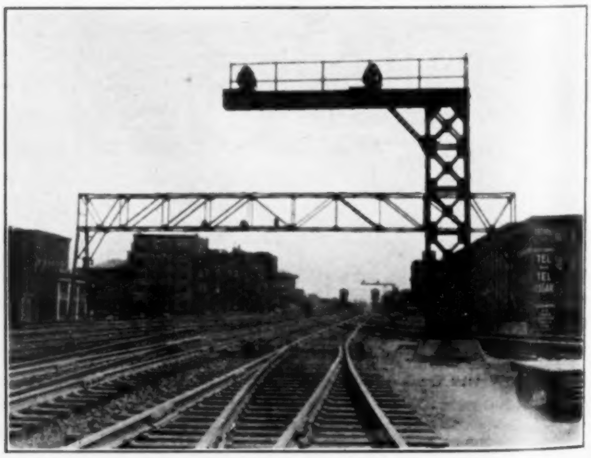

Fig. 7 West End of Track Layout Looking East From Connecticut River

### Telephone Service

In addition to the information conveyed to the operator by the indicator, complete telephone service is provided connecting with train dispatchers, station platforms, and various points on the roadway within the limits of the interlocking. The telephone service is supplemented by the telautograph system with sending and recording sets in the signal station and the dispatcher's office and with recording sets only in the station master's office, station information office, and train bulletin board in the main waiting room of the station.

### Power Supply

Power for the operation of the interlocking is taken from the city service, which supplies two-phase 60-cycle current at 440 volts. Power is distributed through the switchboard, as shown in

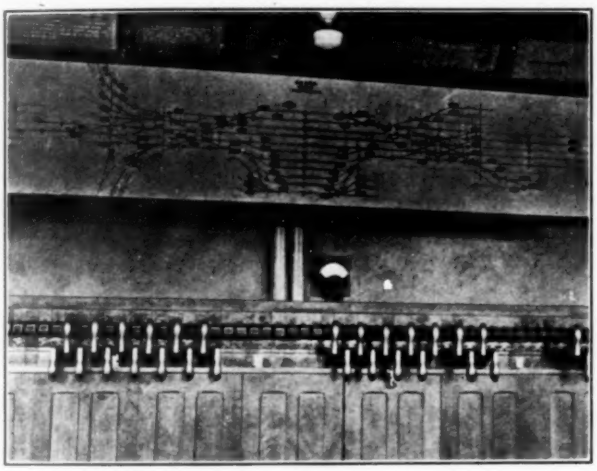

Fig. 8 Track and Signal Indicator Mounted Over Interlocking Machine in Signal Station

Fig. 9. The main battery for operating the switch machines and the low-voltage battery for operating the electric locks, secondary relays, etc., are enclosed-type lead storage batteries. The main battery consists of 60 cells of 350 ampere-hour capacity and the low-voltage battery has two sets of batteries of six cells each in multiple with a combined capacity of 700 ampere-hours. Single-phase 110-volt alternating current is supplied for the operation of the track circuits and color light signals.

The main battery is trickle-charged by a motor-generator set in duplicate. The generator is shunt-wound and supplies 750 watts at 150 volts. The low-voltage battery is also trickle-charged by a motor-generator set in duplicate. The generator is shunt-wound and supplies 750 watts at 15 volts.

In the event of a temporary failure of the commercial power furnished from the city service a d.c.-a.c. motor-generator set is provided which is automatically cut in to furnish the power to operate the interlocking. The set is operated from the main 110-volt storage battery.

### Conclusion

The features of importance in the interlocking system as installed at Springfield, the author believes, have been covered in this paper. Two of these essential features have been considered, namely, those having to do with the safety and with the facility of the system. There are of course two other features, namely, reliability and economy.

Reliability of an interlocking system is primarily dependent upon the fundamental principle underlying its operation. The principle of the system installed by the Boston & Albany, it is believed, is correct, and it therefore follows that the reliability of the system then depends upon a proper design of each and every part of the devices used to put the principle into practice.

The economy effected by a system of this kind is reflected in many ways. If the design of the apparatus is correct, resulting in

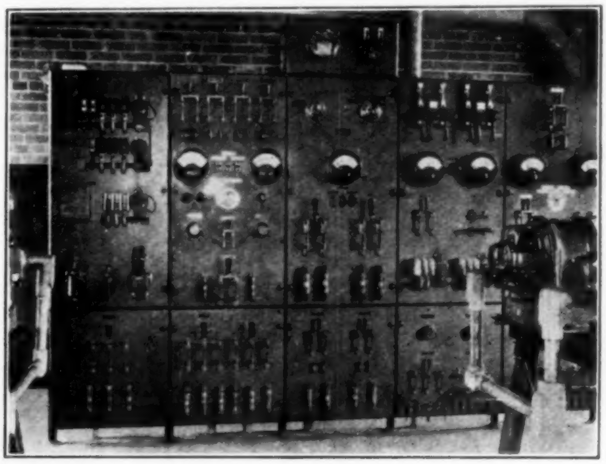

Fig. 9 Power Switchboard

long life, the cost of renewals will be relatively small. The cost of operating also shows a corresponding economy, not only by the fewer men required for an electric as compared with a mechanical system of interlocking, but also in the cost of train operation.

## Discussion

J. J. Corcoran.[3] The author mentioned phantom signal indication. In signal work this is a very important feature. The color displayed by the signal must be only that resulting from the light behind the lens. The signal is designed so that any exterior light that may be reflected from an unlighted lens and thus tend to give an improper indication, is limited as far as possible.

Another feature is that of the trickle charge which is very widely used on most of our railroads. The old-fashioned way was to charge the battery to its full capacity and then let it discharge until it reached the point as far as it was designed to go and then charge it again. This new method calls for constant float charging, thus keeping the battery at full capacity at all times so that there will always be sufficient energy to operate the system for maximum stand-by capacity.

The Author. Mr. Regan asks if this installation on the Boston & Albany has resulted in the discontinuance of two signal stations, one on either side of the Springfield station, and if we can operate the signal station with a smaller force than in the other system. In reply the author would state that the new interlocking replaces two mechanical signal stations that heretofore controlled the traffic into and through the old station. A 48-lever mechanical tower controlled the switches and signals east of the station and a 56-lever mechanical tower controlled the signal layout west of the station. These two signal stations required a force of 14 men for operation for a 24-hour period, whereas the new interlocking is operated by 9 men in the 24-hour period. This marked economy in operation effected by the new electric interlocking as compared with the old mechanical system of interlocking is further increased by a corresponding economy in the cost of train operation. A recent check-up showed that a total of approximately 1015 movements are made by this interlocking in a 24-hour period.

# Locomotive and Freight-Car Utilization

## What the Railroads Have Accomplished in More Effective Equipment Utilization Since 1920

By C. B. Peck,[1] New York, N. Y.

The termination of Federal control of the operation of the railroads of the United States early in 1920 was the beginning of a new era of railroad operation. One of the important characteristics of the new era is the attention which is being given to effecting a more intensive utilization of every facility which enters into the production of transportation. The results are perhaps most strikingly demonstrated in the case of cars and locomotives, with which we are here concerned.

The problems involved in making the most effective use of the available supply of cars are quite different than those involved in making the most effective use of the available supply of locomotives. The car problem is much more complex and, unlike the locomotive problem, is not entirely within the control of the operating departments of the railroad, nor, indeed, entirely within the control of the railroad as a whole. The average car load is more within the control of the shipper than of the railroad, and the frequency with which each car can be made available for loading is also partially within the control of the shipper. Problems connected with interchange between railroads, particularly in keeping a suitable distribution of the supply as between regions and railroads to meet the varying seasonal demands of certain kinds of traffic, are also very complex and beyond the effective control of the carriers, acting individually.

The methods worked out by the carriers since 1920 to make the car supply serve most effectively are generally familiar to engineers interested in railroad problems. The principal features of these methods are the centralized control of car distribution through the agency of the Car Service Division of the American Railway Association in crises which require measures other than those affected by the car-service rules, the reporting of the facts pertaining to car utilization by the Car Service Division, and the opportunity for cooperative action of the railroads and the shippers through the Regional Advisory Boards.

To accomplish the utmost use of each unit of equipment, the principal objectives, so far as the operating department is concerned, are prompt movement and the heaviest practicable loading per car. The former is measured in terms of car-miles per day; the latter, in tons per loaded car. The car loading had decreased since 1920. The promptness of movement, however, as measured in miles per car-day, has markedly increased, and the result has been a progressively improving service to the public both in the promptness with which cars have been furnished for loading and the dispatch with which they have been moved to destination. Prior to and including 1920, each succeeding year of peak traffic was a year of congestion and heavy car shortages. In 1923, in which the net ton-miles handled exceeded the traffic of 1920 by 2 per cent, car shortages, although still present, were less severe in their effect. In 1926, the most recent peak year, with 8 per cent more net ton-miles than in 1920, car shortages had, practically speaking, disappeared entirely. This is a record with which the railroads and shippers alike may be proud.

So much for the character of the public service rendered by the railroads. What has been the effect on the roads themselves? What tendencies has this effort set in motion and how are they likely to affect the future? Perhaps a brief examination of the data bearing on these questions may be worth while in helping to relate to each other at least some of the factors in a situation which, in some respects, is puzzling enough.

The first factor to be considered is net ton-miles, which is the measure of the business handled. The next is the number of cars on line in which the ton-miles have been produced. The next is the number of car-miles required to handle the business, classified as loaded miles and empty miles.

In presenting the picture, I shall make as little reference as possible to the large numbers which must be used to express these various quantities in the aggregate for the Class I railroads in the United States, but since it is the trends in which we are

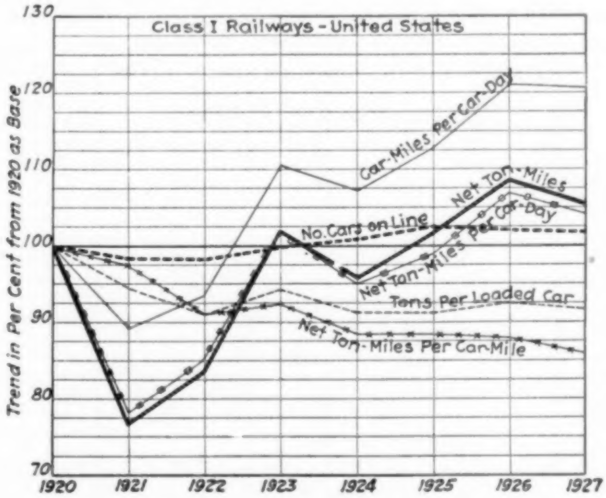

Fig. 1 Trends in Car Performance Since 1920

interested, I shall, in the main, merely indicate the rate of growth or decline since 1920. Those who are interested in the actual quantities for each year will find the data in tabular form.

In Fig. 1 is shown the trend in car utilization from 1920 as shown by the average tons of freight handled per loaded car, the average miles per car-day, and the net ton-miles per car-day. This shows the proportion to which the car load has dropped off since 1920 and how the car-miles per car-day have increased at a much greater rate than the business handled, having increased by 12 per cent in 1923 and 21 per cent in 1926, whereas the volume of business moved had increased but 2 and 8 per cent in those two years, respectively. The net ton-miles per car-day is merely an indication of the relation between the gross business handled and the aggregate supply of cars and, beyond this indication, is of little significance.

Fig. 2 shows what actually took place in producing the results indicated by the ratios in the previous diagram. The number of cars on line, which represents the ownership of the railroads plus such privately owned equipment as is actually in service on the rails of the carriers, has remained fairly constant, with a slight dropping off during 1921 and 1922 when business was light, and a gradual increase in 1925 to about 2.4 per cent more

[1] Managing Editor, *Railway Mechanical Engineer*. Assoc-Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers.

than in 1920, from which it has varied but slightly since that time. Loaded car-miles, of course, has followed the trend of the amount of business to be handled. But, whereas in 1923 the net ton-miles had increased only 2 per cent over 1920, the loaded car-miles had increased 7 per cent and, with 8 per cent more net ton-miles in 1926 than in 1920, the loaded car-miles was 16 per cent more than in 1920. This, of course, is the result of the decline in the average car load.

One of the most interesting points in connection with the car performance is the trend in empty car-miles. It will be seen that in 1921 when business declined materially from the preceding year, the aggregate amount of empty car mileage had increased slightly. If fell off in 1922, but not in proportion either to the amount of business or the loaded car-miles, and since that year has continued to increase steadily with the exception of an insignificant decline in 1924. In 1923, with its slight increase in business over 1920, empty car mileage had increased 18 per cent; in 1925, with practically the same volume of business, it had increased $28^1/_2$ per cent, and in 1926, had increased 40 per cent over 1920. Despite the decline in the volume of business handled in 1927, the number of empty car miles had still further increased to 42 per cent over 1920. This, then, is the explanation for the greater proportionate increase in car-miles per day than in loaded car-miles and in the maintenance of practically the same number of miles per car-day in 1927 as in 1926,

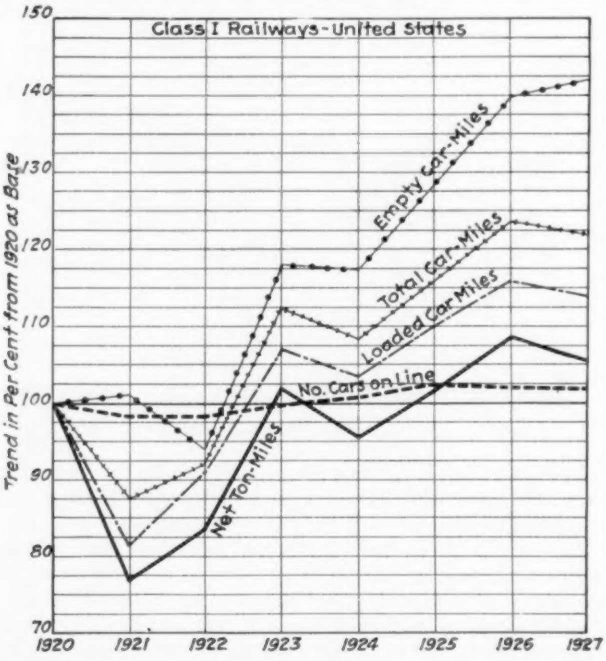

Fig. 2 Trend of Car-Miles in Relation to Net Ton-Miles Since 1920

despite a decline in business and a similar decrease in the number of loaded car-miles.

In 1920 there was an average of 47.3 empty car-miles for each 100 loaded car-miles. As the result of the marked increase in empty car-miles, there has been, with the exception of 1921, a steady increase in this ratio to 52 in 1923, to 57 in 1926, and to 59 in 1927. This is the price which the railroads have paid to make a car supply, which, in 1926, was only about two per cent greater than in 1920, handle a traffic eight per cent greater than in 1920, and to handle it without car shortages. How it was accomplished may become at least partially evident by examining the trend in the percentage of cars owned which are at home on the lines of the owning roads. This is shown in Fig. 3. The curve does not show all of the minor fluctuations reported, but does show major swings and all of the critical points in the curve. At the termination of Federal control in 1920, the freight cars of the carriers were so badly scattered that but 22 per cent were in the hands of the owners. Much the same condition had prevailed throughout the period of Federal control. This was

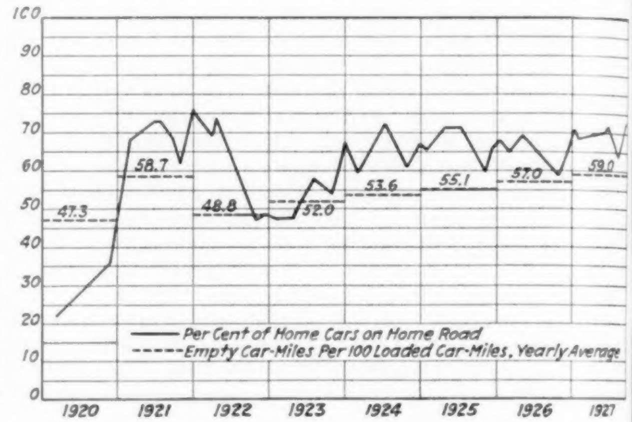

Fig. 3 The Location of Freight Cars With Respect to Ownership

followed by a tremendous home movement late in 1920 and early in 1921, to the effect of which attention has already been called in the increase in empty car mileage which took place in 1921 in spite of a severe decline in traffic. A high point was reached in January, 1922, when 75.9 per cent of the cars were in the hands of the owners. In 1922, with the coal miners' strike beginning on April 1 and the shopmen's strike beginning on July 1, the cars were again considerably scattered and but $46^1/_2$ per cent were in the hands of the owners when the downward trend was checked in November.

In the face of this unsatisfactory distribution of cars, the railroads handled the largest volume of business ever handled up to that time in the same length of time, and at the same time effected a gradual improvement in the location of the cars. During 1924 and 1925 the conditions with respect to car location remained fairly constant at a point averaging somewhere between 65 and 70 per cent, with maximums over 70 per cent and minimums not much under 60 per cent. It is worth noting that during the latter year, with a total volume of traffic practically the same as for 1923 and a fairly uniform distribution of cars, falling off slightly during the heavy traffic period in the autumn, the empty car-miles had increased materially over the number required in 1923, when a marked redistribution of equipment was effected in the face of heavy traffic.

Looking at this curve for the major trends—that is, disregarding the seasonal fluctuations—it is evident that since 1922 cars must have been promptly returned to the owning roads—loaded if possible, but without holding for loads—to maintain the relatively high percentages of cars in the hands of the owners which have prevailed since 1924.

A study of Figs. 1 and 2 shows that for the country as a whole car-miles per day implies something which I do not believe is always kept in mind when using this figure. With a total car supply which varies but slightly from year to year, car-miles per day varies in proportion to variations in total car-miles. The use of this figure, then, as a measure of overall effectiveness of car utilization places a premium on empty car-miles, which tends to swell the total without actually producing any net ton-miles of revenue movement.

As an indication of what, from a purely operating standpoint, may be considered as a measure of the efficiency with which cars are used, I believe it is permissible to divide the total number of net ton-miles moved by the total number of car-miles, empty

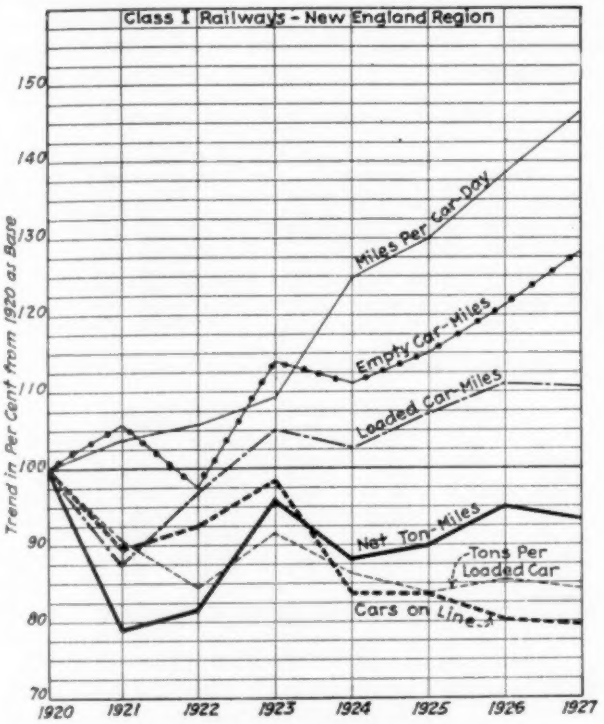

FIG. 4 CAR PERFORMANCE IN THE NEW ENGLAND REGION

and loaded combined, to see how much revenue-producing service each car-mile is rendering. The trend in this unit is shown in one of the curves on Fig. 1. It will be seen that this has been constantly declining since 1923.

This does not mean that car-miles per day is not a good unit when applied to individual railroads because it immediately reflects changes in the number of cars on the line, which do not take place when considering the roads as a whole. An accumulation of cars increases the divisor and, therefore, decreases the quotient, other conditions being equal.

How the number of cars on line affects the trend in car-miles per day is indicated in the graphs for the New England and Pocahontas regions, respectively, on Figs. 4 and 5. In the former a marked decrease in the number of cars on line from 1924 to 1927, inclusive, had a material influence in causing a proportionately much larger increase in the miles per car-day than took place in the number of car-miles. In the latter case it will be seen how an increase in the number of cars on line since 1920 has reduced the proportionate increase in car-miles per day below the proportionate increase in the number of car-miles.

While the curves show that empty car-miles are increasing much more rapidly than the aggregate service required from the total supply of freight cars, it must be remembered that what has been shown is the relationship of various trends, which does not in any way indicate the relative importance, or "weighted value" of the factors they represent in their effect on operating economy. This may, in a measure, be judged by the trend in the ratio of empty to loaded car-miles, in Fig. 3, or by the relationship between loaded car-miles and total car-miles as shown on Fig. 2.

### THE CONDITION OF FREIGHT CARS

There is another matter which must be considered before leaving the subject of freight-car utilization; that is, the conditions of the freight-car equipment during the years under consideration. Have equipment conditions been one of the causes of the splendid service results, or has the intensive service been a cause for the equipment conditions? I think it will appear that the equipment conditions have been in a measure both cause and effect.

In considering the trend in car conditions the general character of the curve in Fig. 3 showing the percentage of home cars on the owning lines should be kept in mind, remembering particularly the extremely low percentage which prevailed during 1920, the tremendous home movement late in 1920 and early in 1921, and the marked scattering of the equipment again during 1922. With this in mind, the curves on Fig. 6 will show what has been the condition of the equipment. The lower curve

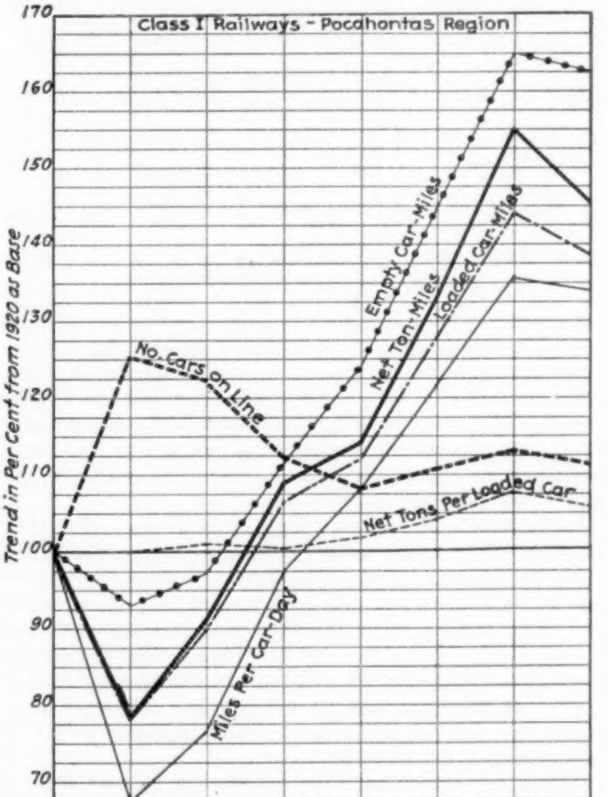

FIG. 5 CAR PERFORMANCE IN THE POCAHONTAS REGION

on this graph shows the number of hours of labor of men employed in car repairs paid for monthly by the Class I railroads. The figures are shown for a single month in each quarter of the year which I believe is sufficient to indicate the trend.

The upper curve shows the average yearly percentage of the cars owned which were unserviceable during the period. One may readily trace the effect of the 1922 strike with its accompanying scattering of the cars and disruption of the car department forces, and also the effect of the falling off of business in 1924 with the accompanying curtailment in the amount of labor devoted to car repairs. The striking thing about the situation, however, is the marked and steady decline in the percentage of bad-order

cars since 1924, with the accompanying decline in the amount of labor devoted to the maintenance and repair of cars.

It is evident that the intensive effort to rehabilitate freight cars, inaugurated in 1923, following the strike, has done more than merely to patch up the equipment, or the proportion of bad-order

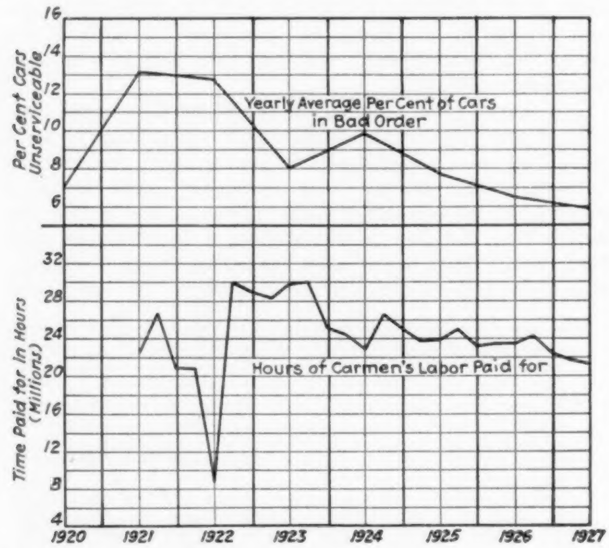

Fig. 6 Monthly Hours of Car-Repair Labor and the Percentage of Freight Cars Unserviceable

cars would not have continued to decline in the face of a decreasing amount of maintenance labor. Further evidence of this is also afforded by the fact (not shown on the diagram) that both the number of cars receiving heavy repairs and the number receiving running repairs has gradually declined through the same period. Had running repairs shown a tendency to increase, it would indicate an accumulation of deferred maintenance, but the contrary is actually the case.

The increase in the car supply available for use indicated by the decline in the percentage awaiting or under repairs has played its part in the character of the service which the railroads have been able to render. The large proportion of the cars which have at all times been on the lines of the owning roads has, in turn, been one of the causes for the constantly improving condition of the equipment. The cost of maintenance tends to decrease as the percentage of cars at home increases. Each road does a thorough job to its own cars but makes only temporary repairs to foreign cars.

Further information as to the condition of the equipment is afforded by the curves in Fig. 7. The curves at the top of the graph show the total car ownership of the Class I railroads at the end of each year and, since 1920, the average number of cars on the lines daily for each year. The lower curves, all of which are parallel to each other, have been drawn starting from different dates to show cumulatively from 1911, 1916, and 1920, respectively, the number of cars installed. It will be seen that a number of cars equal to 80 per cent of the cars owned at the end of 1926 were installed during the 15-year period from 1911, 56.7 per cent in the 10 years since 1916, and 31.2 per cent during the six years since 1920.

Attention must be called to the fact that the number of cars installed does not represent the number actually built new. This will be evident by an inspection of Fig. 8. During the years since 1920 many of these installations represent cars retired from the records of the carriers, rebuilt, in the main with betterments, and reinstated on the books of the carriers. Something of the extent to which this was done may be evident from the fact that 232,000 cars were installed in 1923, while less than 100,000 were ordered during that year, and only 180,000 had been ordered from the builders during the preceding year. Two hundred fourteen thousand cars were retired, however, in 1923, in the heavy rehabilitation program which followed the strike. A considerable percentage of these cars were undoubtedly rebuilt and reinstated.

TABLE 1 FREIGHT-CAR PERFORMANCE

| Year | Net ton-miles (000,000) | Freight car-miles (000,000) Total | Empty | Loaded | Empty in per cent of loaded | No. freight cars on line | Per cent of ownership | Per cent unserviceable |
|---|---|---|---|---|---|---|---|---|
| 1920 | 449,125 | 22,607 | 7,259 | 15,384 | 47.3 | 2,469,000 | 104.4 | 7.0 |
| 1921 | 344,343 | 19,819 | 7,335 | 12,484 | 58.7 | 2,425,000 | 103.6 | 13.2 |
| 1922 | 375,617 | 20,808 | 6,831 | 13,977 | 48.8 | 2,426,000 | 105.0 | 12.8 |
| 1923 | 457,590 | 24,993 | 8,569 | 16,424 | 52.0 | 2,463,000 | 106.3 | 8.0 |
| 1924 | 429,453 | 24,448 | 8,535 | 15,913 | 53.6 | 2,486,000 | 106.2 | 7.8 |
| 1925 | 456,265 | 26,230 | 9,323 | 16,907 | 55.1 | 2,526,000 | 106.6 | 7.7 |
| 1926 | 488,578 | 27,974 | 10,154 | 17,820 | 57.0 | 2,520,000 | 106.8 | 6.5 |
| 1927 | 474,683 | 27,791 | 10,312 | 17,479 | 59.0 | 2,509,300 | 107.0 | 5.9 |

TABLE 2 FREIGHT-CAR PERFORMANCE—AVERAGES

| Year | Average weight per car, tons | Average car capacity, tons | Net tons per loaded car | Car-miles per car-day | Net ton-miles per car-day | Net ton-miles per car-mile |
|---|---|---|---|---|---|---|
| 1920 | 20.1 | 42.4 | 29.3 | 25.1 | 498 | 19.9 |
| 1921 | 20.4 | 42.5 | 27.6 | 22.4 | 389 | 17.4 |
| 1922 | 20.5 | 43.1 | 26.9 | 23.5 | 424 | 18.1 |
| 1923 | 20.7 | 43.8 | 27.9 | 27.8 | 509 | 18.4 |
| 1924 | 20.9 | 44.3 | 27.0 | 26.9 | 472 | 17.6 |
| 1925 | 21.1 | 44.8 | 27.0 | 28.3 | 493 | 17.6 |
| 1926 | 21.4 | 45.1 | 27.4 | 30.4 | 532 | 17.5 |

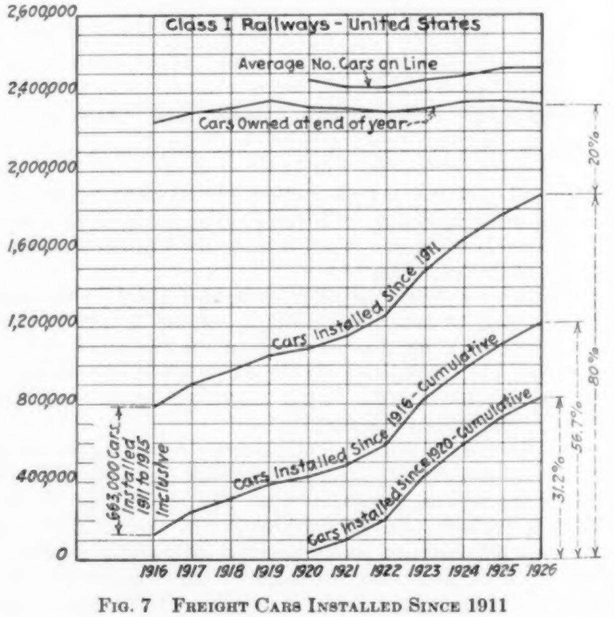

Fig. 7 Freight Cars Installed Since 1911

How far were these reinstated cars improved with betterments? It is impossible to answer this question, except in a very general way, without an actual inventory of the equipment. An indication, however, may be obtained by examining the trend in the proportion of cars of all-steel or steel underframe construction. In 1915, 52.1 per cent of all freight cars of railroad ownership were of all-steel or steel underframe construction. In 1920 this proportion had increased to 65.2 per cent, the increase having been maintained with a fair degree of uniformity throughout the five years. In 1925 this proportion had increased to 75 per cent, the trend again being fairly uniform.

The great bulk of freight cars of railroad ownership are included in two classes—box cars and open-top cars, or coal cars

In the former group are included between 46 and 47 per cent of the total ownership and in the latter, a little more than 40 per cent. In 1915, 38.6 per cent of all of the box cars owned by the Class I railroads were of all-steel or steel underframe construction mostly the latter. In 1924 this proportion had increased to 64.5 per cent and, in 1925, to 67.6 per cent. In the case of coal cars, 71.3 per cent were of steel or steel underframe construction in 1915, 89.1 per cent in 1924, and 90.5 per cent in 1925. These figures indicate a steady improvement in the character of construction which, of course, is a major factor in the ability today to maintain the equipment in a highly serviceable condition with a minimum of labor.

There is one other trend which is worth while considering before concluding our attention to the freight-car situation. That is indicated by the curves in Fig. 9 which show the rate at which the average capacity and average weight of freight cars have increased since 1920. It will be seen that the two increases have almost coincided. It will also be seen that the proportion of average car capacity which is actually utilized has declined since 1920.

Returning for a moment to Figs. 4 and 5 illustrating the trend in freight-car utilization in the New England and Pocahontas regions, respectively, one may see what a relatively small part of the potential carrying capacity of the cars is actually utilized in territories where no coal originates and how the tendency is downward under such conditions. Starting with an average car load of 24.6 tons in the New England region in 1920, it has declined to 20.7 tons in 1927. The Pocahontas Region, on the other hand, is made up of coal-carrying railroads, and car loading in this region has increased from 42.1 tons in 1925 to 45.3 tons in 1926, with a slight decline to 44.9 tons in 1927. This represents the effect of the heavy coal movement which, as the graph indicates, has grown rapidly during the past few years.

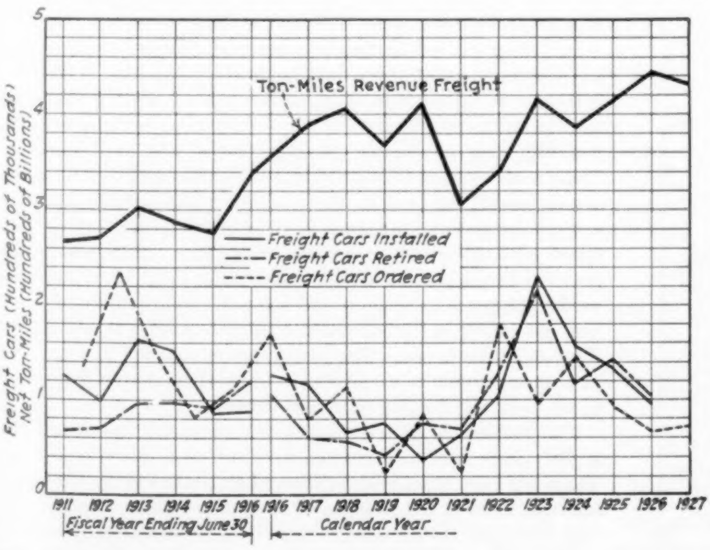

FIG. 8 FREIGHT CARS ORDERED, INSTALLED AND RETIRED ANNUALLY SINCE 1911

Before leaving cars, it may perhaps be well to bring together in a brief summary the salient features of the situation. The car ownership of the Class I railroads has shown little tendency either to increase or decline since 1920. It has been supplemented by a slightly increasing proportion of cars of private ownership, mostly of special types such as refrigerator and tank cars. The physical condition of the equipment has steadily improved, large numbers of cars having been rebuilt with betterments by the carriers, notably in 1923. With each succeeding increase in business, this fairly constant number of cars has rendered a slightly increasing amount of service, but the promptness of the service has increased very materially. More car loadings

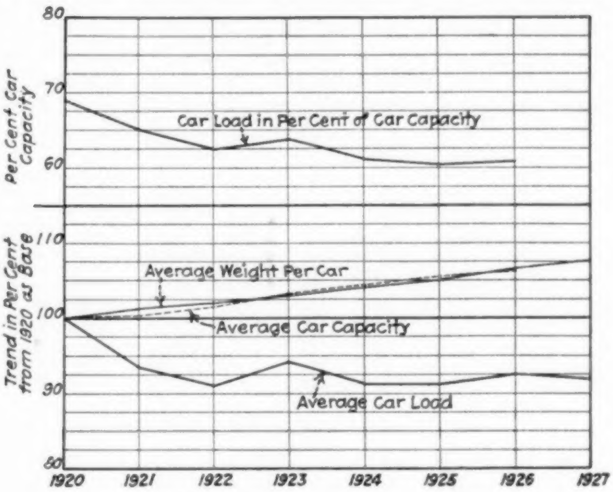

FIG. 9 CAR LOADING IN RELATION TO CAR CAPACITY

TABLE 3 FREIGHT LOCOMOTIVES

| Year | On line | Stored | Per cent unserviceable | Active locomotives | Average tractive force, lb. |
|---|---|---|---|---|---|
| 1920 | 30,081 | 669 | 24.3 | 22,102 | .... |
| 1921 | 32,891 | 3,939 | 24.0 | 21,158 | .... |
| 1922 | 32,859 | 2,932 | 25.5 | 21,552 | 42,452 |
| 1923 | 32,976 | 1,481 | 21.6 | 24,380 | 43,706 |
| 1924 | 33,230 | 3,827 | 18.8 | 23,153 | 45,300 |
| 1925 | 32,450 | 3,712 | 17.8 | 22,968 | 45,840 |
| 1926 | 31,639 | 2,775 | 16.4 | 23,679 | 46,750 |
| 1927 (11 months) | 30,570 | 4,707 | 16.1 | 20,943 | 48,000 |

have been required because of the decline in the average load. This improved service has been effected at the expense of a marked increase in empty car-miles. This increase in the proportion in 1926 over that in 1920 required the operation of approximately 3.5 per cent more freight train miles and, in 1927, approximately 4.4 per cent more train miles than would have been necessary had the 1920 ratio of empty to loaded car-miles prevailed in those years. The aggregate cost of this extra car mileage was about $100,000,000 in 1926 and $120,000,000 in 1927. The average freight-car capacity and weight continue to increase steadily, while the average car load has declined since 1920. There is little reason to expect it again to increase and the very efficiency with which the carriers are serving the public suggests the possibility of a further decline, from reductions in size and increases in the frequency of merchandise shipments.

Shall this condition continue unchecked? May it not be possible that some of the increased empty car mileage could be traded at a profit for more cars? May it not be time for car designers to study the problems of weight and capacity, particularly of box cars, in the light of changing conditions?

### LOCOMOTIVE UTILIZATION

What has happened in the use of locomotives since 1920 is fully as remarkable as what took place with respect to freight cars. Fig. 10 shows the number of locomotives, both in freight and passenger service, with which the railroads have handled their business. There was an average of 30,081 freight loco-

motives on the lines of the Class I railroads in 1920. The number increased slightly following 1920, declining again to 30,570 during 1927. Since 1922 there has been a steady decline in the percentage of unserviceable locomotives, the effect of which on the total number of serviceable locomotives is indicated by the second line from the top of the graph. There has been considerable fluctuation in the number of freight locomotives stored serviceable since 1920, the number decreasing in the years of heavy business like 1923 and 1926. By deducting the stored

locomotives from the serviceable, the freight locomotives which may be considered as being in active service are shown by the third line in the graph.

How has this locomotive supply been used? There was a

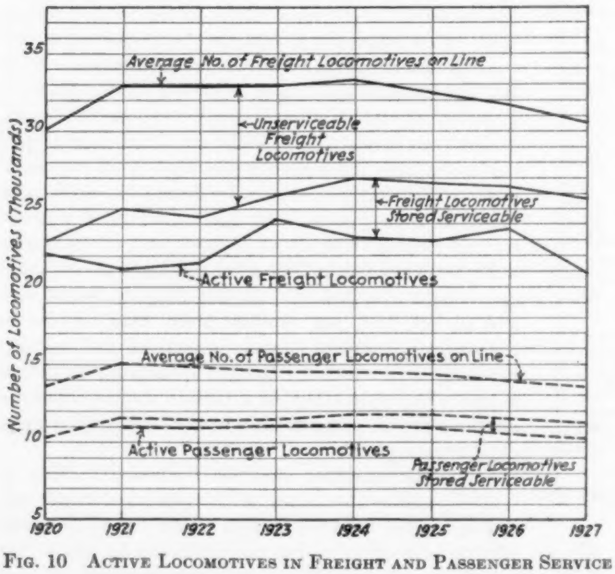

Fig. 10 Active Locomotives in Freight and Passenger Service

decline in the intensity of the use of the active locomotives following 1920 which is indicated by the average miles per year which these locomotives made. Starting with 32,500 in 1920, the average freight-locomotive mileage dropped to 28,000 in 1921, and with the exception of a slight decline in 1924, it increased steadily but slowly until it reached 30,100 during the peak year of 1926. What is most striking is the fact that with the decline in business in 1927, the actual use of the active locomotives has shown a marked increase to an average mileage of 33,000. This is illustrated in Fig. 11.

Beginning with 1922, for which the figures are first readily available, the average tractive force of locomotives in freight service was 42,452 lb. This increased steadily until in 1927 it had reached 48,000 lb. During the same period the gross train load had increased from 1466 tons to 1780 tons. In Fig. 12 it will be seen that this increase in train load was considerably greater than the increase in the average tractive force of the locomotives, indicating a better average utilization of the potential tractive capacity. This improvement, in the face of the increase in average train speed from 11.1 miles per hour in 1922 to 12.3 miles per hour in 1927, indicates a splendid performance. The combined effect of this increase in train load and train

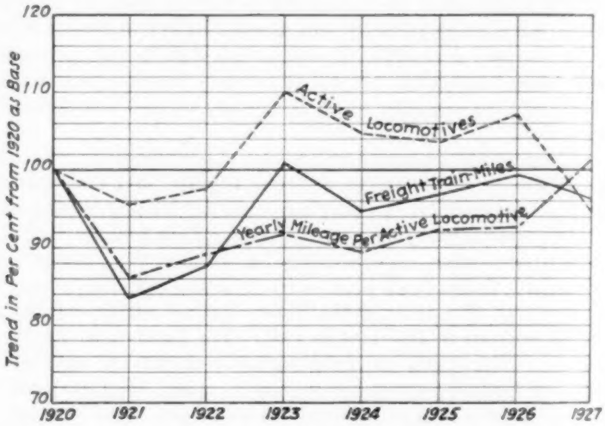

Fig. 11 Trend in Yearly Mileage per Active Freight Locomotive

speed is indicated by the gross ton-miles per train-hour which were 35 per cent greater in 1927 than in 1922.

So far as the locomotive is concerned, this is a reflection of the tendency toward increased horsepower capacity in modern locomotives. Attention must, however, be called to the fact that locomotive utilization is affected by the character of other facilities such as signals, passing tracks, and yard facilities. There was a period following the termination of Federal control during which the lack of these facilities in adequate quantity exercised a material influence in keeping down the average train speed and materially increasing train-hours. Long delays on poorly located passing tracks and equally long delays awaiting yard track space in which to put away the train at the end of the run, not infrequently consumed from one-quarter to one-half of the total train-hours. The performance reflected in Fig. 12 is in part the result of a constantly improving coordination of all of the facilities affecting train movement.

The number of active passenger locomotives has varied but slightly since 1921, as is indicated by the lower curves on Fig. 10. There has been a decrease in ownership, a decrease in unserviceable locomotives, but an increase in the margin stored serviceable. The variation in the relationship of passenger train-miles, the number of active locomotives, and the yearly average miles per active passenger locomotive has been much less than the variations in the similar relationships for freight locomotives. It is, however, interesting to note on Fig. 13 that since 1921 there has been a steady, although not large, increase in the miles per active locomotive per year until 1925, and a much greater increase in 1926.

It is in passenger-train service that the most effective results are obtainable from long locomotive runs. The movement toward increasing passenger-locomotive runs has been progressing

steadily for several years and has undoubtedly been the major influence in producing this increase.

It was possible to show clearly the relation between the increase in the average tractive force of the locomotives and the gross tons per train in freight service. The data are not available from which to show this relationship with equal clearness in the case of passenger locomotives. There has been a steady increase in the average tractive force of passenger locomotives just as there has been in the case of freight locomotives. In 1922 the average was 26,745 and in 1927 it had reached 30,800 lb. The average passenger train in 1922 consisted of 6.4 cars and had increased to 7 cars in 1927. How this increase in the train length compares with the increase in the tractive force of the locomotives is indicated in Fig. 14.

The average length of the passenger train, however, does not

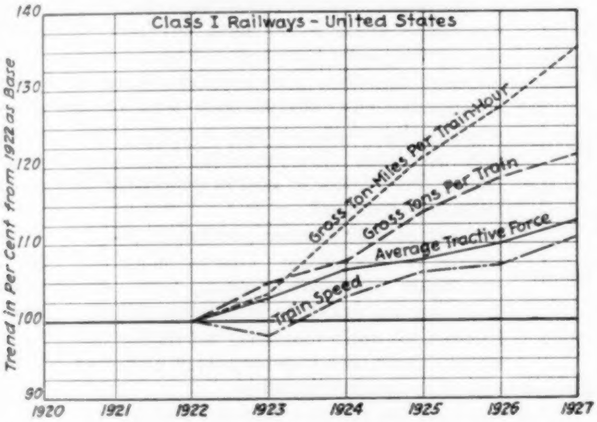

Fig. 12 The Relation of Train Load to Tractive Capacity and the Trend of Ton-Miles per Train-Hour

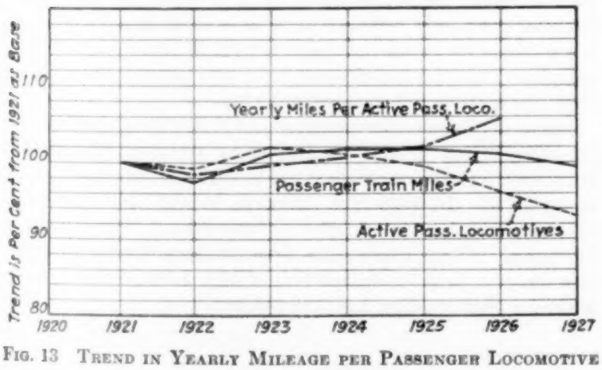

Fig. 13 Trend in Yearly Mileage per Passenger Locomotive

tell the whole story. In 1922, of the 6.4 cars per train, an average slightly less than 2.0, probably about 1.8, were sleeping, parlor, or dining cars. Probably about 2.5 cars of the 7-car train in 1927 were of this heavy type of equipment. Furthermore, there has been a steady increase in the number of steel and steel underframe coaches, baggage, and express cars, with a corresponding decrease in the number of wood cars. The total number of passenger cars of railroad ownership in service has not changed materially from between 54,000 and 55,000, but at the beginning of 1923, 24,000 of these cars were of steel or steel underframe construction and, in 1927, some 34,000 were of steel or steel underframe construction.

How far this increasing weight of the average car of railroad ownership and the increasing number of Pullman cars in the train has tended to increase the weight of the train above that indicated by increase in length, it would be very difficult to say.

TABLE 6 PASSENGER-TRAIN PERFORMANCE

| Year | Train miles (000) | Locomotive miles (000) | Average cars per train | Average miles per day, all locomotives | Average miles per year, active locomotives |

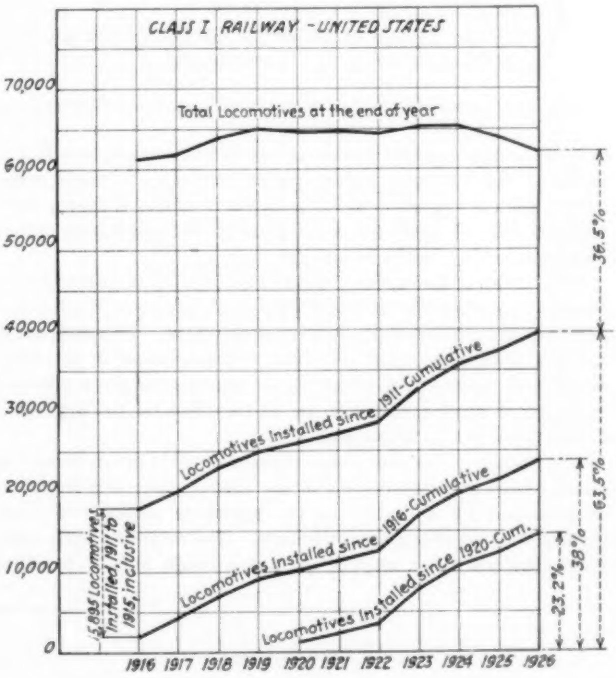

Fig. 15 Locomotives Installed Since 1911

## Locomotive Conditions

In the discussion of cars, an attempt was made to show what the railroads have done in keeping up the quality of the cars in service. Much the same information is available for locomotives. Fig. 15 has been prepared to give some idea of the age of the locomotives now in service. It will be seen that of the 62,400 locomotives in service at the end of 1926, 63.5 per cent were installed since 1911. In other words, approximately 64 per cent of the power in service at the end of 1916 was then 16 years old or less. Of these locomotives, 23,700, or approximately 38 per cent of the total locomotives in service, had been installed since 1916 and were 10 years old, or less, and 14,700 or approximately

25 per cent of the total number of locomotives, had been installed since 1920 and were not over 7 years old.

Here the term "installed" implies the same thing as it did in the case of cars and if one follows the curves on Fig. 16, it will be evident that many locomotives which were installed in 1923 were old locomotives which were rebuilt either in the shops of the roads

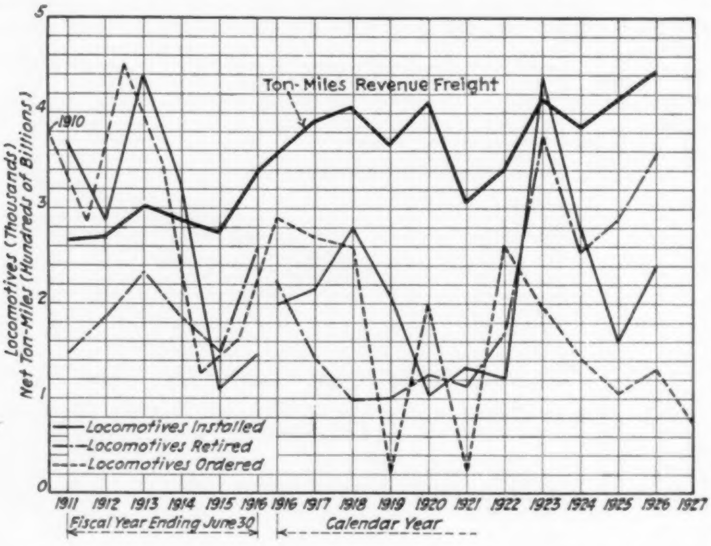

Fig. 16 Locomotives Ordered, Installed, and Retired Since 1911

or in contract shops and accounted for as new locomotives in the books of the carriers. These locomotives were in most cases rebuilt with betterments and, though not wholly modern, they are probably all equipped with some of the appliances which characterize the modern locomotive.

An interesting fact brought out in Fig. 16 is the large number of locomotives retired in 1925 and 1926, with relatively small numbers of locomotives installed during those years. This suggests a marked clean-up of obsolete power. The decrease in the total number of locomotives which these retirements have effected has been of small moment so far as its effect on the aggregate locomotive capacity is concerned.

The decline in the percentage of unserviceable locomotives has already been mentioned. As in the case of cars, this has been accompanied by a decline in the aggregate amount of labor expended in locomotive maintenance. The monthly hours paid for machinists' labor may be used as a rough index. Starting with about 12 million in the fall of 1921, there was a heavy reduction during the strike to a low point of about $4^{1}/_{3}$ million. By January, 1923, a high point of almost 16 million was reached. There was a decline to 12 million by the middle of 1924. Following a rise to $13^{1}/_{3}$ million at the end of the year, there have been no further sharp changes, the average remaining between 12 and 13 million throughout 1925 and 1926. The average during 1927 has been slightly under 12 million, in keeping with the decline in the business handled last year.

The essential facts pertaining to the locomotive situation may be summarized as follows: There has been a relatively small change in the number of locomotives in service since 1920. Increases in the number of locomotives during the first years of this period have been offset by decreases during the past three years. No immediate shortage of power is indicated, however. The condition of the power has improved and, owing to more intensive use, there is an increased reserve of serviceable locomotives. Freight train-miles continue to decrease owing to the increase in unit tractive capacity and train load. The increasing train speed has decreased train-hours in greater proportion than train-miles have decreased.

There is still another problem of utilization with respect to locomotives. That is, taking advantage of the highly developed traveling power plants which have become available within the past five years—locomotives which materially exceed the capacity possible to obtain within the range of proportions commonly adhered to no more than five years ago.

When one considers that the splendid performance, particularly in freight-train service with its reduced train-hours and greatly improved fuel economy of the past three years, must have been in great degree the result of the better coordination of facilities previously referred to, it is evident that there is still a big future for continued improvement in these respects when completely modern locomotives come into use in sufficient numbers to make their influence generally felt.

Major dependence for improvement in operating economy was for many years placed on increasing tractive capacity and train load. Each train-mile saved in this way, at present, saves about \$1.50. In 1926 each overtime freight train-hour saved by the Class I railways effected an average saving of \$9.10 for wages. At their face value these facts would seem to emphasize the rich field for locomotives of high horsepower capacity, wherever crew overtime has to be paid for.

## Discussion

William Elmer.[2] As the representative of the motive-power department, it has been the duty of the writer to prepare engines and cars for service on the road. It has been a gratification to many of the railroad men who, perhaps, looked farther ahead, to see their ideas at last come to fruition.

A new engine house was built at Altoona a few years ago, and many labor- and time-saving devices were installed. The writer's opinion is that not all of those features were appreciated at the time, but as the years went by, those devices to quicken operation became of the utmost importance. Looking back on the records that were made, and recalling the fact that 400 engines were handled each day at that one terminal, it is gratifying to know that the railroads have been able to keep up their end in this procession of progress and to help make the figures which the author has presented. He has painted an excellent bird's-eye view of the work that has been done in the last few years, and he is to be congratulated on the manner in which he has picked out those things which have produced this remarkable showing by the railroads.

The details, of course, he could not handle in a general survey such as he made. These are taken from the usual statistics which are accessible to all railroaders and the public in general if they care to look them up. Some of the developments that made those figures possible are intensely interesting.

Intensive effort from the highest to the lowest officer is required to obtain the performances which have made possible the figures which the author has given. Railroad officers who have either heard or read this paper must realize that it is their duty to continue these splendid performances and improve upon them.

[2] Special Engineer, Pennsylvania Railroad Co., Philadelphia, Pa. Mem. A.S.M.E.

Roy V. Wright.[3] We can learn a great lesson, as engineers, by studying the causes of the remarkable records mentioned by the author. A railroad officer in a recent discussion of operating conditions on a 110-mile division stated that not many years ago freight-train crews carried most wonderful dinner pails—pails costing several dollars each and large enough to carry three or four meals. Today these men carry no dinner pails. They eat before leaving home, and they get their next meal at the other end of the run, since it is regularly made in four and a half or five hours. Formerly trains were tied up on this division because of the "hog law"—the 16-hour law. Today this law has been forgotten on this particular division. Why?

If we study operating conditions of a few years ago, we find that there were a great many things that caused delays. For one thing, departmental lines were too strongly drawn. Then, too, the executives did not realize the necessity of giving the mechanical department greater responsibility and support, in order that the equipment could be kept in the best of condition at all times.

In 1922, when the railroads were becoming desperate with continued congestion, the American Railway Association wisely set up certain goals toward which to strive. As a result, all of the railroads got into a big game and less thought was given to departmental lines. Railroad men as a whole got the idea that they were working not so much for their particular department as for a great organization, whose duty it was to get freight and passengers over the road; they went into it in a spirit of play, as if it were a great game.

When the ball is started in motion in a football game, ten men on the team devote their efforts to clearing the way for the man carrying the ball, in the effort to prevent his being interfered with. Today, when an engineman is given an engine with a train behind it, every one gets busy in doing his part to prevent the train from being stopped, in order that it may get over the road as quickly as possible. Then, too, tremendous amounts of money have been expended to provide double or multiple tracks, longer sidings, better locomotives and equipment, improved signals, and car retarders in freight-train yards. Main-track trains are frequently run 1000 miles or more without being broken up at division points as in former days. As Secretary of Commerce Hoover stated a year ago, the shipper and the receiver of freight can depend upon material's being delivered on schedule time. This has been a great factor in stabilizing business.

# Car Retarders, a Recent Development in Railway-Yard Operation

By L. Richardson,[1] Boston, Mass.

One of the important operations in railway transportation is the sorting or classifying of cars at division or terminal yards. During the past 25 years the so-called hump yard has been generally conceded to be most economical means of classifying cars. The hump yard has one or two tracks on an ascending grade to a summit, over which a train of cars is pushed by a humping engine, usually at a speed of two to four miles per hour. The cars are uncoupled or "cut" by the conductor of the humping crew just before reaching the summit, and then run by gravity down the far side of the hump into the proper classification track. On gravity humps car riders or brakemen control the speed of the cars down the hump and ladders to prevent them from running into other cars standing on a classification track at a speed that might damage cars and lading. Two miles per hour for loads, and a corresponding higher rate for empties, is considered as a safe coupling speed. The riders climb on the cars before reaching the hump, one to each car or group of cars, known as a cut, try the brakes to see that they are operating properly, ride the car until it reaches its classification track, and after checking the speed of the car to about 3 miles an hour either walk back to the hump or are carried there by a motor car on a special track. A considerable part of the car rider's time is therefore spent in returning to the hump, and unless traffic is fairly uniform he also spends much time waiting for trains to be humped. Obviously the capacity of a yard depends upon the number of riders available. Where traffic is uniform it is not difficult to provide a suitable number of riders, but where traffic varies greatly, as is the case in most yards, it would not be economical to provide a sufficient number of riders to handle peak periods promptly. During such periods it is necessary to wait for riders, while at other times the riders are idle.

The number of cars that can be handled by a rider in a day, or an 8-hour trick, varies considerably, depending on the length of the classification tracks, on whether he walks or rides back, and on the average number of cars per cut. From 25 to 50 cars per rider is the usual practice. A car rider's wages are about $7 for an 8-hour trick.

Ordinarily track switches are thrown by switch tenders, the number depending on traffic. In some yards the switches are power-operated and are controlled from a lever machine at or near the hump. The number of 8-hour tricks worked per day, as well as the number of engine crews on each trick, also depends upon traffic.

### Usual Arrangement of Car-Rider Yard

The usual hump yard has one or two tracks from the hump and one or more ladder tracks, along which at regular intervals are the classification-track switches. This arrangement is essential with hand-operated switches so that the switch tenders can walk or run along the ladder tracks and seldom have to cross tracks.

Grades vary greatly, but it is usual to have a short stretch of 3 or 4 per cent just below the hump and then 1 per cent extending some distance into the yard. In certain cases the 1 per cent grade begins at the hump and extends nearly to the end of the yard.

The height of a hump can be computed approximately, and then raised or lowered until it is suitable for the requirements of the yard and for the character of the traffic handled. In general a higher hump is required for empty cars than for loads, and also for winter conditions as compared with summer ones. In some yards the height of the hump is increased a foot or two before winter begins, and lowered the same distance in the spring. In other yards two humps are provided, a high one for winter and a low one for summer.

The disadvantages of car-rider operation are as follows:

- Unsuitability for sudden peak demands.
- Cost of riders, switch tenders, and other employees.
- Personal injuries to employees.
- Damage to cars and lading.
- Pilferage of cars by riders and other employees at night.
- Cleaning yard of coal, etc., falling from cars.

### Development of the Retarder

In order to reduce the cost and to eliminate the hazard of hump operation, experimental tests were conducted by President Hannauer of the Boston & Maine (then vice-president of the Indiana Harbor Belt) and his associates at their Michigan Avenue car shop with a device for the retardation of cars moving on tracks.

The principles developed here were then applied in a retarder placed on the west-bound Gibson hump on September 15, 1923, consisting of two 40-ft. sections at the foot of the incline of the hump. These machines were first operated by four-way air valves from a central point, they being placed in a small building at the foot of the hump, and later by electropneumatic valves. The latter displaced the hand throw and simplified the work of the retarder operators, making it possible for them to handle the cars with greater rapidity.

The first tests were successful, but the question then came up as to the action during extreme cold weather, especially when accompanied by snow. These tests were continued later in 1923, during cold weather and snowstorms, and as no adverse effect was noted in the operation, this led to further installations early in 1924. Operation was then continued with four retarders, other units being added, until in December, 1924, the west-bound yard was completely equipped.

The first retarders were constructed from convenient railway materials, such as car springs and brake cylinders. Refinements in design have progressed to the point where practically every member has been designed for the required service and manufactured accordingly.

The car retarder (Fig. 1) is a track brake which presses against both sides of the lower part of the car wheels in the same manner as a vise, the pressure being controlled by an operator according to the weight and the speed of the car—heavy retardation for a heavy load and little or no retardation for an empty. There are two types of car-retarder systems in service on the railways of the United States—the all-electric system, in which retarders, switch machines, and skate machines are controlled and operated by electric energy, and the electropneumatic system, in which similar units are controlled by electric energy and operated by compressed air.

## Details of Retarder Construction

The shoe beams are of special alloy steel, 5 ft. 6 in. long, articulated to prevent binding due to variation in the grade of the track. The top of the brake shoe is 2 in. above the top of the rail. The wheel space is 7 in. open and 4 in. closed. Every third tie is a steel I-beam. Car retarders are ordinarily 33 ft. to 40 ft. long. The latter is the maximum length operated by one mechanism; if greater lengths are required, two or more units are used. The weight of a 33-ft. retarder and mechanism is approximately 16 tons and of a 38-ft. 6-in. retarder approximately $18^1/_2$ tons. The construction of a retarder is

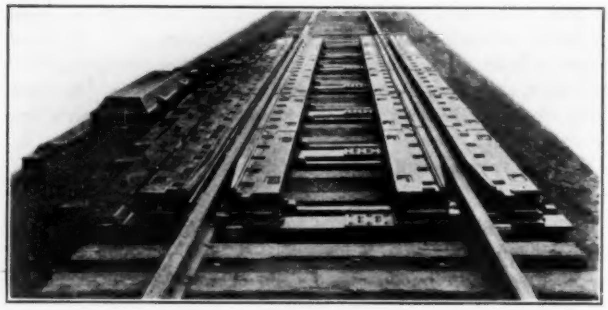

Fig. 1 Heavy-Duty All-Electric Car Retarder

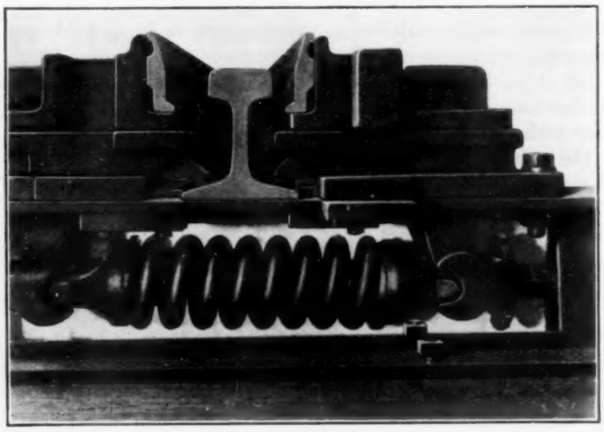

Fig. 2 End View of Retarder, Showing Heavy Springs

such that there is little chance of any dragging car equipment's fouling the retarder, and also a derailed car could do little damage owing to the heavy and substantial parts, capable of bearing the weight of a car or a locomotive. The cranks are mounted in heavy longitudinal members bolted to the ties. The long arm of the crank is attached to a longitudinal operating bar, which is connected to the mechanism. The short arm of the crank is connected to cross-members which operate the spring mechanism under each rail. There are 12 sets of springs for the 33-ft. retarder and 14 sets for the 38-ft. 6-in. retarder. Each set has two springs, making a total of 24 and 28 springs, respectively. Fig. 2 is an end view of a retarder member, showing the heavy springs, and Fig. 3 shows a complete electropneumatic retarder.

All forces are self-contained in the mechanism. Under extreme conditions the maximum stress in the members is not over 30,000 lb. per sq. in. and under normal conditions about 15,000 lb. Wood ties are 8 × 12 in., usually of creosoted oak; similar ties 4 × 10 in. provide a good bearing for the steel ties.

In an all-electric retarder the mechanism case is bolted to a longitudinal angle and two ties near the middle of the retarder. It houses a 230-volt 5-hp. motor with suitable gear reduction, a powerful brake that holds the motor stationary and is released only when power is applied to the motor, and a master circuit controller consisting of five sets of contacts, or one set for each position of the lever in the control machine. Control circuits are 115-volt and operating circuits 230-volt. For simplicity and for economy in wire the operating circuits are local, and the master circuit controller in the mechanism controls heavy-duty forward and reverse contactors in a separate housing at the main power line, usually within 50 or 60 ft. of the retarder. In connection with the heavy-duty contactors there is a time element device that opens the operating circuits in case of excessive current if the motor stalls, thus preventing injury to the motor. A fused knife switch is provided to cut off power during inspection or maintenance. The plan of an all-electric retarder is shown in Fig. 4.

The mechanism is attached to the longitudinal operating bar by means of a toggle arrangement, as shown in Fig. 5, which produces a fast movement when the retarder begins to close and a slower movement with enormous pressure near the closed position. The fast movement near the open position affords a quick release. The diagram also shows the spring mechanism and connections which afford equalization of shoe pressure and compensate for variations in the width of the wheels and of the track gage. This feature largely eliminates the possibility of lifting light cars through the application of heavy pressure. Should by any chance a car be lifted, the inner shoes serve as guard rails, and the car would drop back on the rails on clearing the retarder.

In the electropneumatic type the air-operating cylinder is mounted parallel to the track. The air pressure is controlled by electrically operated valves and is transmitted by a "live-lever, dead-lever" arrangement similar to the foundation brake gear

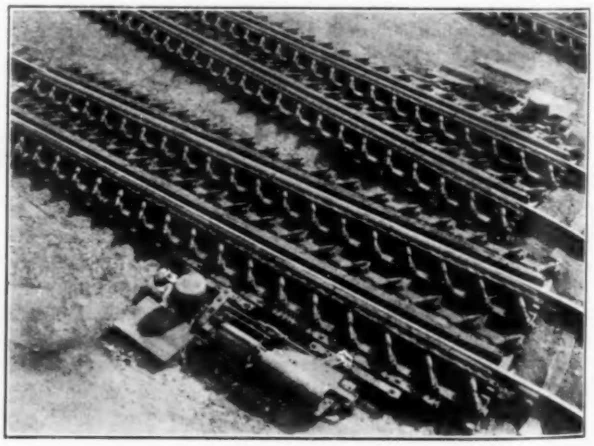

Fig. 3 Electropneumatic Retarder

of a freight car, through bell cranks and springs to the retarder shoe. The pressure is graduated in four steps, and release is accomplished pneumatically, requiring only half the amount of air needed for application, owing to the trunk-piston construction used. Working pressures run as high as 80 to 110 lb. per sq. in.

To take care of wheel-dimension variations very heavy springs are used in the final transmittal of pressure to the shoes. Ample margin is provided so there is no danger of their breaking when subjected to heavy-duty service.

The general practice in handling cars is to set the proper degree of retardation in each retarder before the car reaches it.

as this requires much less current, and also causes less wear on the parts. In some emergencies it is necessary to close a retarder with a car passing through it, usually where proper retardation has not been given in preceding retarders, but this should be avoided if possible.

### Control Machine

The control machine (Fig. 6) consists of a compact steel cabinet with a sloping top divided into panels, which can be raised for inspection of the apparatus. On each panel there is provision for retarder levers, switch levers, skate switches, lever lights, and the name plates for the levers. Each machine has levers for the particular requirements of track layout and retarders. The lever lights, when illuminated, show the operator that the retarder has operated to the corresponding position of the retarder lever. The retarder lever in the all-electric machines has six positions; power off, retarder open, and four degrees of retardation, all of these positions being numbered. The electropneumatic machines have as high as five degrees of retardation, those in Boston having four. The machine and operator are shown in Fig. 7.

Small lights, usually placed just above the switch lever, indicate the normal and reverse positions of the track switches. Where track circuits are used, there is a light for each one which indicates whether a car is on the circuit. With track circuits it is impossible to throw a switch under a car. Ordinarily the retarders are operated to the proper position before a car reaches them, strong retardation for a heavy car and little or none for an empty, as this requires much less current than when a retarder is closed with the wheels of a car therein. In the lower part of the cabinet is a terminal board with panels on which are mounted the main switches, bus bars, fuses, and terminals.

There is usually one lever machine in each control tower, but where two operators work during peak hours, two lever machines of half the size are provided. In most yards two or three control towers are adequate. The determining factor is the number of retarders, switches, and skates that one operator can efficiently handle. The towers should afford a clear view in all directions of that part of the yard controlled from each, so that the operator may observe the speed of the cars and their relative positions. One tower is some distance below the hump and one or more towers are beyond, on one or on both sides of the yard.

### Power Equipment

The power equipment varies according to the commercial current available and the specifications of a particular railroad, but a typical installation is as follows: Two 25-kw., one 3-kw., and one 1-kw. a.c.-d.c. motor-generator sets, one 240-volt 160-amp. storage battery, and switchboards with control apparatus, switches, meters, etc. Power for operation of the retarder system is furnished by the 25-kw. motor-generators, which are usually operated on 440 or 550 volts a.c. and which deliver 230 volts d.c. Two are installed, one being in regular use while the other serves as an emergency unit. The 1-kw. set is used for trickle-charging the storage battery, and the 3-kw. set to charge at a higher rate when necessary, it being possible to charge by both sets connected in multiple. In case of failure of the commercial current the load is automatically switched to the storage battery, which latter will operate the plant for some time.

The power plant for the electropneumatic type is more simple, consisting of compressors, usually motor-driven, and 6-volt battery circuits for the control. The air capacity is not determined by the number of retarders, but by the number of switch and retarder movements. The power equipment is housed in a small building near the center of the load or in a lower story of one of the towers. Motor-generators, compressors, and switchboards are placed in one room and the storage battery in a separate room so as to avoid injurious effects from the sulphuric-acid fumes.

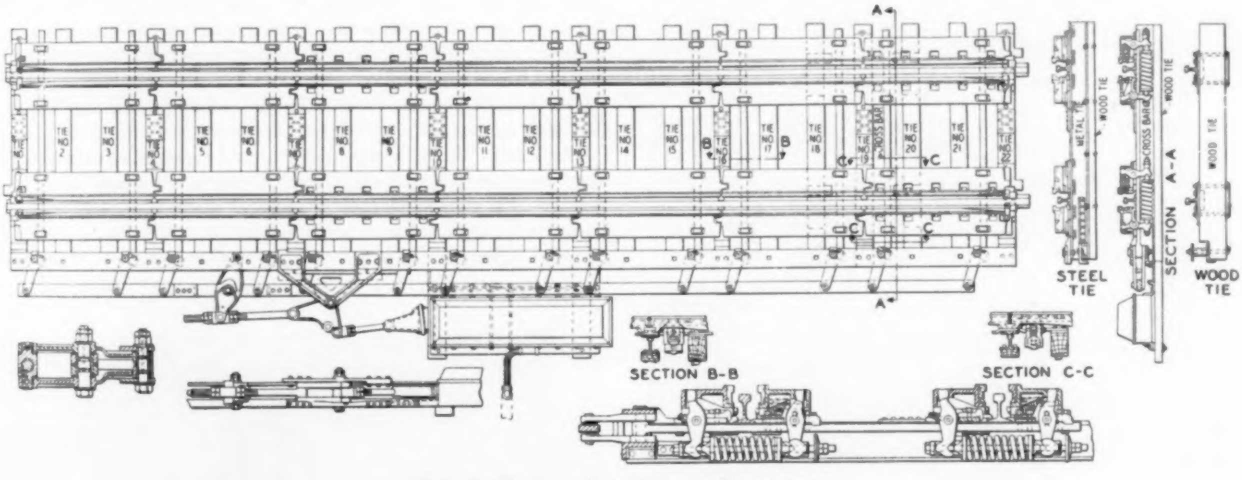

Fig. 4 Plan of All-Electric Retarder

The power required varies with the number of cars handled and other conditions. Figures obtained from one of the first retarder installations show approximately 0.04 kw-hr. per car. Assuming that 1000 cars are handled per day and that current costs $0.03 per kw-hr., the monthly cost of power would be approximately $37.20.

### Switch-Operating Mechanisms

The switch machines which operate the track switches are similar to the switch machines used in electric interlocking, the difference being that some of the protective features not required for low-speed yard operation have been eliminated. Each switch is operated from normal to reverse position or vice versa from a two-position lever in the control machine. The operating time is about one second, which is well under any requirements. The position of the switch is indicated by two lights on the control machine, one light indicating normal position and the other the reverse position. The switch machine follows instantly the position of its control lever. The switch machines are either electropneumatic or all-electric.

The latter operate on 115 volts, one side of the circuit being connected to the 230-volt power line and the other to the neutral wire. A two-indication color-light signal is usually installed at each switch, as shown in Fig. 8, which not only indicates the position of the switch, but serves as a location marker, which is of considerable assistance to the operator at night in spacing cars from the hump. It is the practice of some railroads to install detector track circuits at each switch to prevent the throwing of a switch under a train, essentially the same as in interlocking practice. However, this has a tendency to slow up operation. With well-drilled operators it is not felt that this protection is warranted.

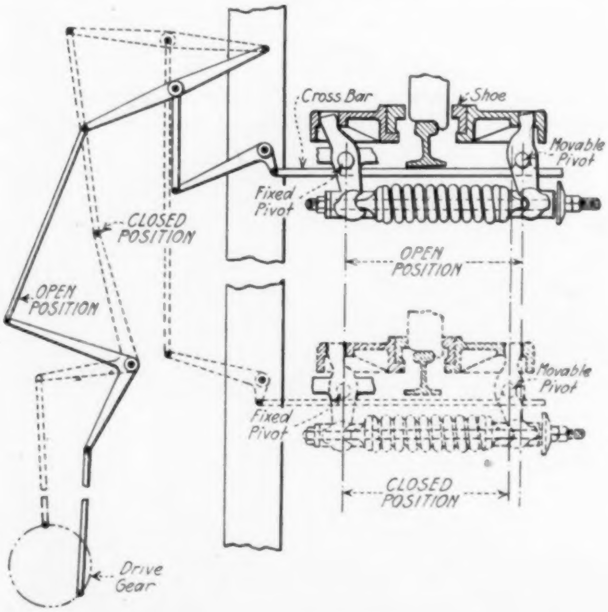

Fig. 5 Diagram Showing Quick-Closing Principle

### Skate and Skate Machine

The skate (Fig. 9), although solely a safety feature, is used on a number of retarder installations, being placed on each track just beyond the frog at the clearance point. The skate is used only in the emergency of a car leaving the last retarder at too high a speed, which might result from improper handling by one or more operators, or in the case where a loaded car was improperly designated as an empty on the operator's list. The skate consists of a steel casting with its upper surface curved, the base of the skate fitting into a supporting frame which is connected to a simple mechanism in such a manner that the skate is raised from its normal horizontal position beside the rail to a vertical position on the rail. The skate machine operates similarly to the switch machine and is controlled by means of a switch on the control machine.

### Humping Trimmer Signals

Engine movements in the yard are controlled by two or more color-light signals, each of which indicates in both directions. One signal at or near the crest of the hump is controlled by the hump engine conductor, who cuts off the cars as they are pushed up the hump grade; the other signals repeat the indications of the hump signal and are located along the hump lead so that an indication is always visible ahead of the humping engine regardless of the length of the train. The aspects and indications vary among the railroads, but the following are typical:

*Signals Facing North or West*

| Color | Indication |
|---|---|
| Red | Stop |
| Yellow | Proceed at normal humping speed |
| Two yellow | Proceed at fast humping speed |
| Green | Proceed at normal yard speed |
| Yellow over red | Back up. |

*Signals Facing South or East*

| Color | Indication |
|---|---|
| Red | Engines in classification yard remain in clear; humping is proceeding |
| Green | Humping has ceased; engines in classification yard may come out on lead. |

The first set of indications governs humping operations and the second set trimming or similar operations. In yard parlance the term "trimming" refers to the pushing into the clear of cars that may foul other tracks, also to pushing cars to the far end of the classification tracks so as to make room for additional cars. In some yards the necessary trimming is done by the humping engine after it has humped a train, and in other yards by another engine known as the trimmer engine, which stands by during humping operations.

The control of the humping signal and repeater signals is such that the operator in the first tower can at all times cause the display of a stop indication in cases of emergency, and in such cases the hump conductor must put his control lever to the stop position before he can give proceed indications. For the information of the operator the indications of the hump signal are repeated in the first tower.

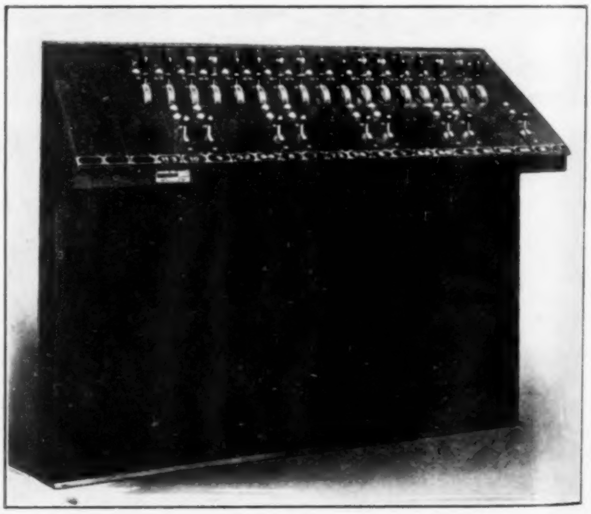

Fig. 6 Control for Retarders, Switches, and Skates

### Wire and Wiring Circuits

The control and operating wires in some cases are placed in wood or concrete trunking supported on wood or concrete stakes, and in other cases they are in the form of cable buried in the ground. The advantage of the trunking arrangement is that the full length of all wires is easily available for inspection in case of trouble. The chief advantage of the cable is that it is out of sight below ground and is not subject to damage by derailments, workmen, etc. There is some question as to which arrangement is the more economical, but both are extensively used.

The wires and cables are usually in accordance with the speci-

fications of the American Railway Association, Signal Section, as car-retarder plants are usually installed by or under the direction of the signal department, as well as being maintained by that department.

### Auxiliary Apparatus

Some of the auxiliary features in a retarder yard, and which are also used in car-rider yards, are as follows:

1 Teletype system, by means of which typewritten lists of cars and their weights are transmitted simultaneously from the yard office to the hump, all towers, and other points where required. Pneumatic tubes are sometimes used for distributing lists.

2 Loud-speaker telephone system, with transmitters and receivers at the hump and each tower, so that the conductor at the hump and the tower operators can communicate with each other easily and quickly.

3 Short-wave radio apparatus for communication between the conductor at the hump and the engineer of the humping engine. A trial of this system has given satisfactory results on one important installation (Selkirk Yard, New York Central), where 125-car trains are humped.

4 Flood lighting, essentially the same as in any hump yard for night operation, but arranged with respect to the view of the retarder operators.

5 Track scales, when required, the same as in any hump yard.

6 Mechanical hump, which provides means for raising or lowering the hump to compensate for the different running of the cars in winter and in summer. With a hump high enough for the worst condition, as an empty car on a cold winter day, and

Fig. 7 Machine and Operator in Tower

with sufficient retarders, a mechanical hump is unnecessary, and one has not been included in a retarder installation since 1926.

7 Hot-oil plants to apply hot oil under pressure to car journals in cold weather to cause the cars, especially the light loads and the empties, to roll freely and so not to delay operations.

### How Retarder System Operates

Retarder, switch machines, and skates are controlled from two or three towers (sometimes four or five towers in very large yards) at suitable places, and the operator in each tower controls all the retarder switches and skates in his section.

When humping operations are not in progress, the jaws of

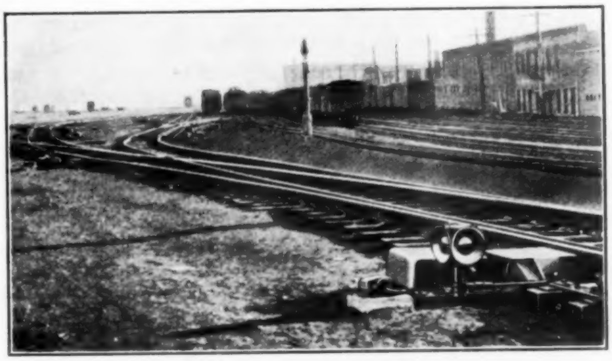

Fig. 8 Electropneumatic Retarders and Switch Machines

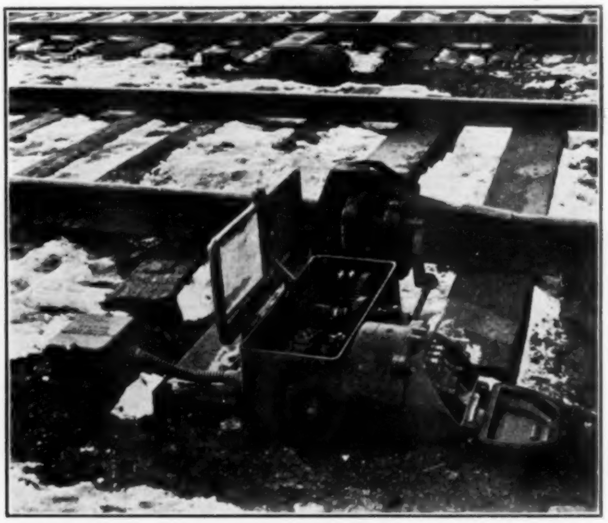

Fig. 9 Skate-Placing Machine

the retarder are open so that engines and cars can pass through them freely. As each cut leaves the hump each operator sets the several switches in position to line up the respective route, and then sets each retarder at one of its four degrees of retardation; in general, heavy retardation for a heavy loaded car and little or no retardation for an empty car. The proper amount of retardation at each retarder depends upon the weight and speed of a car or cut, the necessary spacing to prevent fouling of cars, and the destination of the following cuts. With cars of similar weights a close spacing can be maintained. The most unfavorable condition is a heavy load followed by an empty proceeding to adjacent classification tracks, as it is necessary to apply considerable retardation to the former to prevent acceleration and to allow the empty to proceed with little or no retardation so as not to stop it on the leads and block the yard. Such a case is properly handled by providing a suitable time interval at the hump.

After handling the cars through several retarders they are finally let out of the last retarder at a speed of about 3 miles an hour on a non-accelerating grade, and at which speed they may

bump other cars standing on the same track without damage to cars and lading. The retarder operators quickly become expert in handling the cars under all conditions, and there are records of some remarkable performances where 150 to 200 cars have been humped in an hour.

### Cycle of Operations in Retarder Yard

The operations in a retarder yard vary somewhat according to conditions, but the following are typical:

1 Incoming train arrives at receiving yard.

2 Waybills are delivered to yard office.

3 Inspection of train by yard force; bad-order cars are so indicated and are later switched from the train.

4 Lists showing car numbers, information as to weights (L indicating load, LL for heavy load, E for empty, etc.), and track number or classification to which cars are destined, in the same sequence as the cars stand in the train, are simultaneously transmitted to each retarder operator, to the yard conductor at the hump, and to other points about the yard as required, by means of the teletype machine or pneumatic tubes.

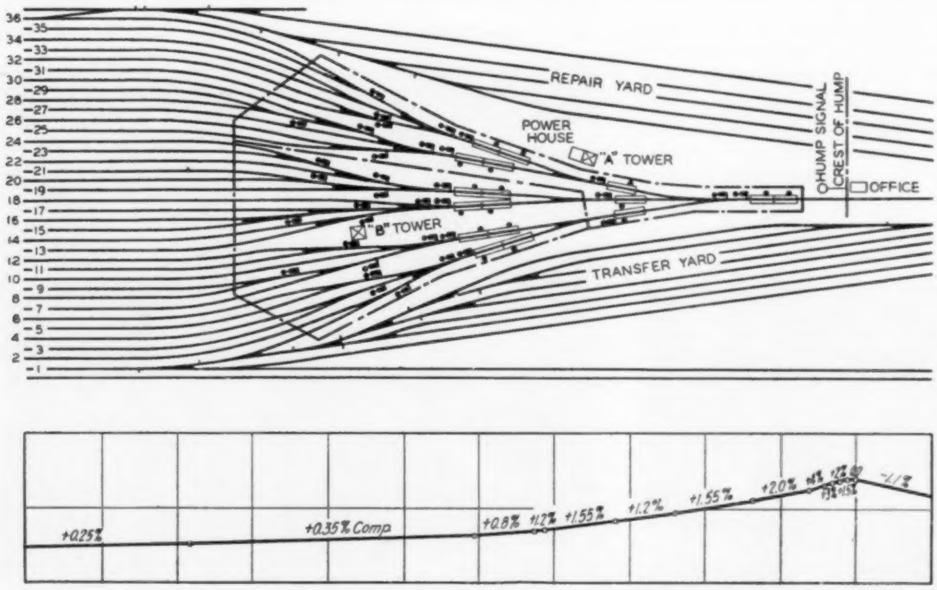

Fig. 10 Track Plan and Profile of Grade of Hump

5 Hump engine is coupled to rear of train, and as soon as humping signal is displayed, pushes the train up the hump.

6 Hump conductor cuts off cars at hump in accordance with teletype list.

7 Retarder operators set switches and retarder in proper position in accordance with teletype list, checking each cut as handled. In cases of emergency the operators also set the skates to stop a car that has left the last retarder at too high speed.

8 Hump conductor gives special information or instructions to operators by means of loud-speaker telephone system.

9 When train is humped, the humping engine and crew do any trimming that is necessary, and then return to receiving yard for another train or engage in other switching operations if there are no trains in receiving yard.

10 Outbound train made up at the far end of classification tracks, leaving from one of the classification tracks or in some cases from a departure yard.

Only part of the time of the humping engine and crew is spent on humping or trimming, the rest of the time being spent in making up trains, delivering transfers, and in miscellaneous switching operations about the yard, in which the retarder operators often serve as part of the crew.

### Operating and Maintenance Force in Retarder Yard

The operating force in a retarder yard comprises one or two engines, each with engineer, fireman, conductor, and two brakemen; a retarder operator in each tower; and the usual yard staff of yardmaster, assistants, clerks, etc., as in any yard of similar traffic conditions.

The maintenance force, under direction of the signal department on account of its being familiar with similar apparatus, usually is made up of a maintainer on each trick during which humping takes place and two helpers on the day trick. The helpers are usually yard section men assigned to the oiling of retarders for a part of their time. The number of maintainers depends upon the size of the plant, traffic conditions, and method of operation, but one maintainer always should be available during humping operations in case something should go wrong.

Maintenance work includes the frequent lubrication of retarders and other mechanism; the replacement of worn retarder shoes, they lasting from several months to a year or more, depending upon their location in the hump, or intermediate, or on classification tracks as well as on the traffic; adjustment to compensate for shoe wear; and the routine inspection and care of the apparatus.

### Arrangement of Tracks and Grades

The maximum capacity of a retarder yard is attained with a group of retarders on each classification track, but the cost of such an arrangement would be very high and the capacity afforded would be far in excess of reasonable requirements. It is therefore the practice to design an arrangement for the particular requirements, and as economy of installation requires a minimum number of retarders, one group of retarders usually serves from three to seven or more classification tracks, according to traffic, number of classification tracks, and other factors.

A typical arrangement is as shown in Fig. 10, in which six leads radiate from the hump lead and each lead serves six classification tracks. There are three groups of retarders: First, the hump which controls the speed of cars at the junction switch and as used also to space adjoining cuts; second, an intermediate group which checks the acceleration of cars or cuts on the comparatively steep grades; and third, the final group which reduces the speed to about 3 miles an hour. The speed of cars through the throat of the yard depends upon the retarding value of the last group. In Fig. 11, the Mechanicville yard of the Boston & Maine Railroad, there is shown a total of 17 retarders, or about one retarder to two classification tracks, which is a very efficient arrangement. In order to have each car or cut from the hump reach the clearance point in each classification track in the shortest possible time, within the limits of possible humping speed, it is obvious that the distance from the crest of the hump to the clearance point in the classification track should be a minimum.

One method of shortening this distance is the use of lap switches, which also tend to reduce the number of feet of retarders required. Track scales, also any switches on the hump lead, tend to increase this distance and to increase the number of feet of retarders.

### Grades That Are Recommended

The hump and grades recommended by the American Railway Engineering Association or a modification of these are ordinarily suitable for retarder yards. For yards in the northern part of the United States, where there is considerable cold weather in winter, the hump grade should be 4 per cent, 1 to 1.5 per cent on leads, and 0.25 or 0.30 per cent from last retarder down nearly to the end of the classification tracks; 0.30 per cent is generally assumed as a non-accelerating grade for average conditions, but is subject to considerable variation.

Car friction varies greatly with the type of car, the weight of car, and lading, the temperature, condition of the bearings, the wind pressure, the speed, and the grade, running from 0.25 per cent (5 lb. per ton) for loads to 1.50 per cent (30 lb. per ton) or more for empties. It is a simple matter to provide suitable hump and grades for a yard handling all loads or all empties, but as most yards handle both empties and loads, it is necessary to provide for them or delays in operation would result.

A most unfavorable condition is handling an empty car on a cold winter day. The other extreme is a heavy load on a warm summer day. With mixed traffic, empties, and loads, car retarders afford a simple means of compensating for the difference with a hump of sufficient height to handle an empty car in winter. At several busy retarder yards hot oil under pressure is applied during cold weather to the car journals just before the cars reach the hump, the journal-box lids being raised by the car inspectors in the receiving yards. This method is very satisfactory and prevents the slowing up of operations by a car stalling on one of the leads and the resulting delays which would be critical during peak periods. The journals are warmed somewhat while the train is run from the receiving yard to the hump, which is often some distance; but in very cold weather it is sometimes necessary to run the cars back and forth before humping them.

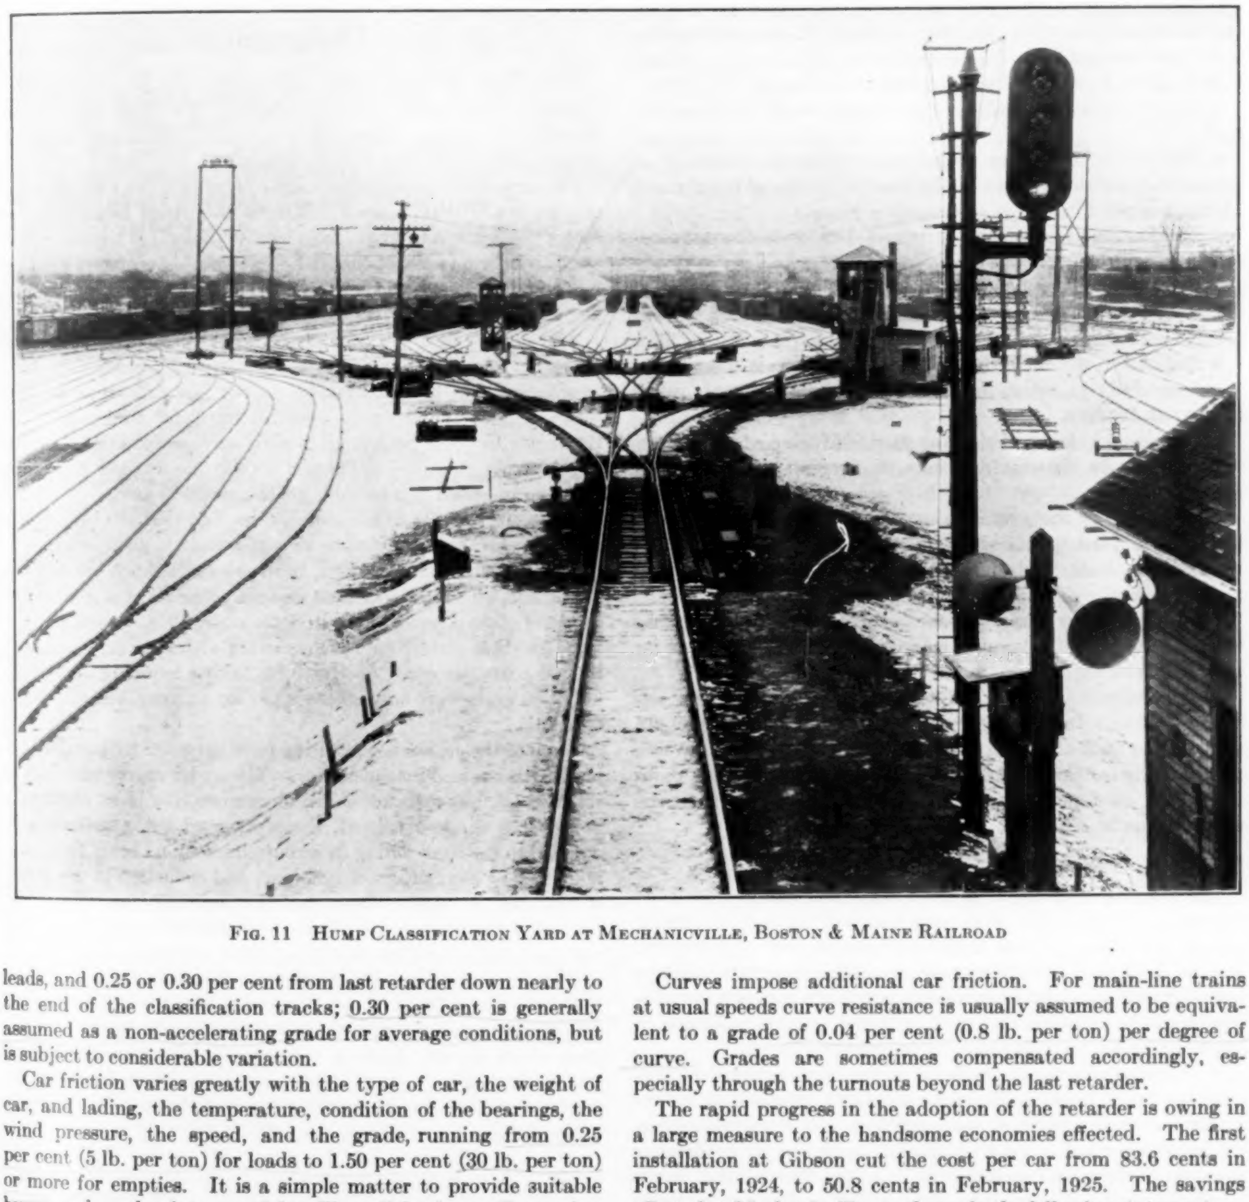

Fig. 11 Hump Classification Yard at Mechanicville, Boston & Maine Railroad

Curves impose additional car friction. For main-line trains at usual speeds curve resistance is usually assumed to be equivalent to a grade of 0.04 per cent (0.8 lb. per ton) per degree of curve. Grades are sometimes compensated accordingly, especially through the turnouts beyond the last retarder.

The rapid progress in the adoption of the retarder is owing in a large measure to the handsome economies effected. The first installation at Gibson cut the cost per car from 83.6 cents in February, 1924, to 50.8 cents in February, 1925. The savings effected at Mechanicville are shown in the following statement:

| | 2 mos., 1927 | 2 mos., 1928 |
|---|---|---|
| Cars received | 50,193 | 51,298 |
| Freight payroll, dollars | 56,621 | 30,961 |
| Cost per car, cents | 112.8 | 60.4 |

| | 2 mos., 1927 | 2 mos., 1928 |
|---|---|---|
| Locomotive repairs, dollars, decrease of | ... | 3151 |
| Fuel, dollars, decrease of | ... | 4355 |
| Hostling, dollars, decrease of | ... | 887 |
| Total saving for two months, dollars | ... | 34,053 |
| Total saving per year, dollars | ... | 221,312 |

### Economy of Retarder Operation

The principal economies resulting from retarder operation may be summarized as follows:

1 Reduction in engine and crew hours. In most yards the humping engine and crew spend only part of the time on humping operations and the rest on making up trains, delivering transfers, or on miscellaneous switching operations. This makes it possible to effect a considerable reduction in the engine hr. per day.

2 Retarder plant available for maximum traffic 24 hours per day.

3 Various flat switching operations at adjacent points or at several stations can be done at the retarder yard and often make a large reduction in engine and crew hours.

4 Elimination of car riders, switch tenders, and other employees and of injuries to these employees.

5 Reduction in damage to cars and lading. On account of the facility of controlling cars by retarders, the humping or coupling of cars at excessive speed is eliminated.

6 Reduction or elimination of pilferage, which is often a big item, especially at night, in a large yard with many car riders and switch tenders.

7 Reduction in labor of cleaning yard. Much coal and similar commodities are shaken from cars on account of coupling at excessive speed.

8 Reduction in the average time required to handle a car or train in the yard. This also tends to reduce the elapsed time between terminals, and thus results in more economical operation on the entire division.

9 Quicker deliveries to shippers. In several cases this has been the subject of favorable comment to railway officials by large shippers.

10 Elimination of accidents and delays resulting from defective brakes. In car-rider yards defective brakes often are not detected until after a car has passed over the hump, in which case the rider is helpless and the car crashes into other cars, damaging both cars and lading, and delaying operations until the wreckage can be removed.

### Cost of Retarder Installation

The cost of a retarder installation varies considerably with the number and gross weight of the cars handled, the height of hump necessary, revision of track layout and grades, and other factors. Also on account of the difference in conditions each yard requires a special study in order to determine whether a retarder installation would be economical. Ordinarily the possible reduction in engine and crew hours is the chief determining factor.

In planning new hump yards for either rider or retarder operation the track layout and grades should be arranged as for retarder operation, which is more efficient and economical than the usual rider hump yard by the reason of the short distance from the hump to the clearance point in the classification track, which naturally shortens the time and the distance required for riders to return to the hump. A yard so constructed and operated at first with riders could easily be equipped for retarders and with minimum expense.

### Conclusion

The car retarder is one of those modern time- and labor-saving devices that have enabled the railways to reduce operating expenses in spite of rising costs of labor and materials. Although the retarder is a recent development, the first commercial installation in the United States was put in service in February, 1926, and nearly all of the apparatus of this first installation is still in service. The design of this first apparatus has been substantially improved, based upon careful observations under service conditions, and the improved design, which has been in service nearly a year, amply meets all requirements, showing that the retarder has successfully passed through the development stage and is now generally considered as an approved device for the efficient and economical operation of hump yards.

## Discussion

Edward E. Regan.[2] The paper covers the operation of car-retarder hump yards very thoroughly. We have one on the New Haven road at Hartford, installed in connection with the construction of the new hump yard there.

Our experience as to the economies resulting from car-retarder installation is that in some instances they were large, but one factor that should be given considerable thought is the size of the yard and the number of cars to be handled. Another is whether all the economies that could be effected in the existing plant had been made before considering retarder installation.

The author lists the number of employees necessary to the operation and maintenance of the plant. Of course, each yard is different, but at Hartford we do not add full crews when a second engine is put on to assist in humping, but require the conductor to cover both engines with only one additional brakeman. When humping is finished we use the retarder operators, who are qualified conductors, on the second engine. With respect to the number of maintainers, we find that one maintainer and his helper are sufficient to keep the plant in good order.

As to the cost per car, on the basis of cars received our costs at Cedar Hill with rider operation and including all men in the yard as based on two typical days in September, 1928, were about the same as those shown for Mechanicville with retarder operation, i.e., 60 cents per car. At Hartford, taking humping operations only, our costs were only 23 cents per car as compared with their 60 cents.

Some of the economies resulting from car-retarder installations have been stressed by the author. The writer agrees with him in this respect, but does not think there were very large economies in some of the items listed, those excepted being reduction in damage to cars and lading (a recent check by us bears this out), reduction or elimination of pilferage, and reduction in the labor of cleaning the yard. These last two especially are under the control of the supervisory officers and should be well in hand in any yard, and therefore should not show any great economy.

The writer does not wish to give the impression that the New Haven is not in favor of retarder yards, but has desired to call attention to some of that company's experience in figuring economies which did not show up very large in the items questioned and would not show such large economies as those listed by the Boston & Maine, possibly owing to the fact that our present man-ridden humps are operating very efficiently.

Charles E. Barba[3]. Since the earning capacity of our transportation systems is, in a measure, equal to the amount of tonnage that can be moved efficiently, yard and terminal facilities un-

[2] General Superintendent, New York, New Haven & Hartford Railroad, New Haven, Conn.

[3] Mechanical Engineer, Boston & Maine Railroad, North Billerica, Mass. Mem. A.S.M.E.

doubtedly control the amount of cars that can be economically classified for road service. The paper very ably describes the methods by which the efficiency of yard operation can be increased, and when we consider that a period of nearly forty years elapsed before any radical change occurred in speeding up yard operations, the following historic facts may be of interest:

Probably the first published statements about gravity yards were made by Professor Kopcke, of the Dresden Polytechnic School, in 1871, when he described the yard at Dresden, which has been in use since 1846. It had its beginning from a natural grade in the main line of 1 in 55, and it is estimated that it was possible to classify at that time (1871) 720 cars in 24 hours. There have also been gravity yards at Leipzig since 1858 and at Zwickau since 1861.

In England, during the year 1873, Mr. Footner claims to have designed the first yard where cars were to be classified by gravity without the use of locomotives or horse power. At this time the London & Northwestern R.R. found that their business at Edgehill, near Liverpool, had quadrupled, but the yard facilities had only been doubled. The company owned land on the north side of the railroad which was available for extensions, but to reduce it to the grade of the main line would have made necessary a large amount of excavation, and it was this fact that led Mr. Footner to design the yards for gravity shifting. It was thought necessary to have some means of stopping cars which might get beyond control of the shunters. Mr. Footner designed what was known as the "chain drag." This consisted of a heavy iron chain placed in a wrought-iron tank between and below the level of the rails; a steel hook attached to the cable was fixed in a loose socket at the height of the car axles and was controlled by a lever. The hook was lowered if the car was intended to pass, but raised if it were desired to stop the car, so that the hook caught the car axles and the heavy chain was dragged over the ballast, thus quickly stopping the cars. It is stated that during the 12 years previous to 1889 it was used 135 times, and that it always stopped the car with no damage to it or to the apparatus itself.

In France gravity yards were first used in 1863 at Terre Noire, near St. Etienne.

The summit or hump yard was used in Germany at Speldorf in 1876 and a little later at Gray, near Essen. In France it was used on the P.L.&M.R.R. in 1888. In the United States it has several claimants for priority. The Honey Pot Yard on the Sunbury Division was built about 1888, and it is also claimed that the Coxton, Pa., Yard on the L.V.R.R. antedates the Honey Pot Yard by several years.

The first artificial hump constructed on the Pennsylvania Railroad, and probably in the United States, was constructed about two miles south of Greensburg, Pa., in the years 1882 and 1883.

R. J. Hammond.[4] The retarder that the author described is an old-type machine.

Mr. Regan spoke of the number of men required. At Boston we have practically the same organization as he outlined for Hartford, that is, one conductor at the hump, regardless of the number of engines. At Mechanicville, on account of the difference in character of the work, we use a conductor with each engine, the engines being used not only at the hump, but to switch in the ice-house and transfer yards, as well as to make delivery of trains to other railroads.

In making a comparison of costs no true result can be reached unless the work done at each yard is the same. Mr. Regan mentioned the cost at one of his stations. The writer does not know how much of the total terminal work is included in his figure. The cost that the author gave was for the period shortly after the retarders were put into service. The last two months our cost has been about 47.2 cents per car received. That is our entire terminal cost, and includes the switching of the transfer, repair tracks, ice house, making up of locals, engine-house work, as well as the hump cost, and in addition includes the cost of industrial-plant switching for private concerns.

The operation at Cedar Hill which Mr. Regan described is different from what it originally was at Mechanicville, as at Cedar Hill all the switches are power-operated, while at Mechanicville they were formerly thrown by hand; the actual labor cost at Cedar Hill, of course, being lower, as one man would do the work from a tower which would require many men to do by hand.

# Locomotive Sparks

By L. W. Wallace,[1] Washington, D. C.

*The annual loss due to fires alleged to have been started by locomotive sparks is stated in the paper to be approximately 12 million dollars. Numerous locomotive and laboratory tests have been made for the purpose of determining the behavior of such sparks, and the author presents some of the findings relating to the subject. It is his belief that under the most favorable circumstances it is very unlikely that a spark of sufficient size and temperature ever reaches the ground in a condition that will ignite even the most inflammable material beyond 65 ft. from the center of the track. Further, there is no direct relationship between wind velocity and spark distribution. Other facts which the author sets forth clearly disclose that it is exceedingly difficult to ignite inflammables with sparks of the size that pass through the ordinary locomotive netting, even at temperatures far exceeding those at which they escape from the locomotive stack. He also discusses other factors with regard to the distribution of sparks, their behavior under conditions of high temperature, color as a basis for judging the temperature of sparks, fire-weather forecasts, moisture content as a reliable index to a degree of inflammability, etc. He is of the opinion that sufficient data have now been accumulated from which fixed laws relating to the behavior of locomotive sparks may be formulated.*

IN THE discussion of the subject of locomotive sparks before a meeting of The American Society of Mechanical Engineers a few years ago, a prominent forester said that before the attitude of the forester can be changed, tests as to the distribution of sparks of fire-bearing size, under conditions of high temperature, low relative humidity of atmosphere, and high wind velocity, must be made. Apparently this forester was not acquainted with all the experimental work which had been done on the subject up to that time.

Numerous locomotive road and laboratory tests have been made for the purpose of determining the behavior of locomotive sparks. There are now available experimental data bearing upon all the points referred to by the forester quoted.

It will be the author's purpose to disclose in this paper some of the findings relating to the subject.

Before proceeding it is well to indicate whether or not the subject is of sufficient importance to warrant discussion and investigation. Federal and State forest officials, in cooperation, have compiled over a period of nine years a record of forest fires by causes. They have formulated eight classifications. The eight classes and the percentage of fires caused by each for a nine-year average are:

| | Per cent | | Per cent |
|---|---|---|---|
| Lumbering | 5.9 | Burning brush | 15.1 |
| Lightning | 7.3 | Unknown | 15.9 |
| Miscellaneous | 7.3 | Camp fires and smokers | 17.5 |
| Railways | 12.8 | Incendiary | 18.2 |

The actual fire damage to forests in 1924 was placed at \$38,000,000. If the 12.8 per cent of fires charged to railways caused the same percentage of damage, they were accountable for \$4,860,000. In official and lay minds this is probably the amount charged to railways. It is an unfair charge, however, because under the railway classification are included all fires starting on the right of way, regardless of the source. Such fires may originate from locomotive stacks and ash pans, or from a cigar or cigarette thrown from a train by a passenger or employee, or dropped by a trespasser. There are numerous ways by which a fire may start on the right of way, and for which the railway is not responsible and which it cannot prevent. Therefore under the present system of classification railways are being officially charged with causing more fires than they themselves are guilty of. This situation should be corrected as it is leading to erroneous impressions as to the liability of railways concerning forest fires.

In addition to the estimated amount of \$4,860,000 forest loss due to fires alleged to have been started by locomotive sparks, which is contended to be erroneous, the railways are subjected to a heavy expense due to the settlement of claims, payment of awards made by juries, and the cost of investigation and litigation resulting from fire cases.

It has been estimated that the total annual cost of fires alleged to have been caused by locomotive sparks is in the order of \$12,000,000. Therefore the spark problem is an important one, and the determination of the behavior of a spark is of such significance as to justify the expenditure of a large amount of effort, time, and money.

### Distribution of Locomotive Sparks

Locomotive sparks are ejected from the stacks of locomotives with considerable force and velocity. This force and velocity affect their distribution. There are other factors which also affect the distances sparks will travel. These are the force and weight of the spark, the force of gravitation, the speed of the train, the force of exhaust, the direction and velocity of the wind, and currents of air created by the movement of the train.

Since so many factors influence the distribution of sparks, no one is justified in drawing any general conclusions from mere observation. Accurate facts as to the distribution of sparks can be determined only by careful experimentation. This has been done, resulting in the following determinations.

1 The greatest amount of material ejected from locomotive stacks falls within 50 ft. of the center of the track. Something like 80 per cent of all the material falls within 50 ft., whereas 98 per cent falls within 100 ft. of the center of the track.

2 The material which falls beyond 70 ft. of the center of the track is very fine and of a sooty character.

3 Sparks of definite weight and bulk fall within 65 ft. of the center of the track. Indeed, by far the greatest number of these fall within 50 ft. No spark of sufficient weight and bulk to carry the amount of heat necessary to ignite the most inflammable material has been caught as far as 50 ft. Indeed, no spark, the temperature of which was gaged to be as high as 1200 deg. fahr., has been caught beyond 25 ft. from the center of the track.

From the numerous observations made, it is the author's deliberate judgment that under the most favorable circumstances it is very unlikely that a spark of sufficient size and temperature ever reaches the ground in a condition which will ignite the most inflammable material beyond 65 ft.

It is an interesting fact that the velocity of wind does not have a material influence upon the distribution sparks. That is to say, if under a wind velocity of 10 miles an hour bulky sparks are caught as far as 25 ft. from the track, it does not follow that if the wind velocity is increased to 20 miles per hour bulky sparks will be caught at 50 ft. There is no direct relationship between

[1] Executive Secretary, American Engineering Council. Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers.

wind velocity and spark distribution. As the wind velocity increases, however, there is a slightly wider distribution of the lighter and sooty material.

This fact confounds people. They do not understand it. The reason is readily appreciated when it is realized that the numerous factors enumerated above control the action of a spark after it leaves the stack—gravity being the predominating one, perhaps.

### High Temperatures

The forester cited earlier queried as to the behavior of a spark under conditions of high temperature. It is taken that he meant atmospheric temperature. Tests have been made with atmospheric temperatures ranging from freezing or below to the normal high temperatures prevailing in the summer. Naturally, as a spark travels through cold air it cools more rapidly than when traveling through hot air, and it is more likely to ignite a substance that is very warm than one which is cold. But under the most favorable atmospheric conditions a spark retains heat for only a very few seconds.

So low is the temperature of a spark upon leaving the stack and so rapidly does it cool, that conditions have to be extraordinarily favorable for it to ignite any inflammable upon reaching the ground, and certainly it does not reach the ground in such a state as to ignite inflammables beyond 50 ft. from the center of the track under high atmospheric temperatures.

Few sparks reach the ground at a temperature as high as 1200 deg. fahr., and those which have been caught at such a temperature fell within 30 ft. of the center of the track.

Laboratory tests have disclosed that a spark must be larger than $^3/_{16}$ in., and at a temperature higher than 1400 deg. fahr., to ignite excelsior. It required a spark $^3/_8$ in. in size and at a temperature of 1400 deg. fahr., to slightly char grass such as the blue grass of Kentucky and Indiana. Such grass does not show a tendency to burn until a $^1/_2$-in. spark at 1600 deg. fahr. is applied. It does not blaze until a spark $^3/_8$ in. or larger, at 1800 deg. fahr. is applied. Sparks $^3/_8$ in. in size do not cause the fuzzy material on the surface of old shingles to flash except at a temperature of 1700 deg. fahr. or above. Practically the same results obtain with new shingles.

Sparks $^3/_{16}$ in. in size produce only a slight char at 1900 deg. fahr. on old shingles, and at 1700 deg. fahr., they cause only a slight discoloration on new shingles. In fact, no spark that can be passed through any netting which is commonly used in locomotives, even when heated to 1700 deg. fahr., will ignite such combustible materials as shingles, sawdust, or light, friable woods.

It will be realized, of course, that temperatures of 1700 to 1900 deg. fahr. are comparable to low firebox temperatures, consequently it is not reasonable to expect that a spark ever leaves the locomotive stack at any such temperature. The average smokebox temperature under the worst conditions is in the order of 750 deg. fahr., or lower.

Burning coal approximately one inch square, taken from a furnace temperature of 1700 to 1900 deg. fahr., and immediately applied to a shingle-roof section, failed to cause ignition. It was not until a piece of coal in the order of three or four inches square was applied that the roof section was ignited, and then it required 42 minutes for a hole to appear in the section.

These facts clearly disclose that it is exceedingly difficult to ignite inflammable materials with sparks of the size that pass through the ordinary locomotive netting, even at temperatures far exceeding those at which they escape from a locomotive stack.

Then, too, sparks cool very rapidly. Two time intervals have been applied. First, the time of visual disappearance of heat, meaning the time in seconds from the removal of a spark from a furnace until no heat can be detected through the appearance of color or smoke; and second, the total time until all the heat in the spark is gone as determined by grasping it with the fingers, the time elapsed being that from the moment the spark was withdrawn until grasped with the fingers.

At 1400 deg. fahr. the visual disappearance of heat from sparks that pass through $^3/_{16} \times {^3/_4}$-in. netting, is 5.4 seconds; sparks passing through $2^1/_2 \times 2^1/_2$-in. square mesh netting, 7.5 seconds; and sparks passing through $^3/_8$-in. netting, 21.2 seconds.

At 1900 deg. fahr., the visual disappearance of heat occurs with $^3/_{16}$-in. sparks in 10.2 seconds, with $^1/_4$-in. sparks in 14.8 seconds, and with $^3/_8$-in. sparks in 21 seconds. At 1300 deg. fahr. the average time in seconds of total disappearance of heat is 53 seconds for sparks that pass through $3 \times 3$-in. square mesh netting and 67 seconds for sparks that pass through $2^1/_2 \times 2^1/_2$-in. square mesh netting; all of the foregoing under the condition of no wind.

The application of wind reduces these time intervals. Under some circumstances with the increase of wind velocity from zero up to the order of four miles per hour there is a slight indication that the time of cooling is increased. This does not appear to be the case under all circumstances, for under some conditions any increase in the velocity of wind from zero decreases the time of cooling. Under all circumstances it may be said that as the velocity of wind increases beyond four or five miles per hour, there is a rapid decrease in cooling time. That is to say, as the wind velocity increases beyond four miles per hour a spark is cooled as the wind increases, and not fanned and made hotter as some believe and contend.

### Color of Sparks

Oftentimes color is used as the basis for judging the temperature or ignition properties of a spark. It is therefore important that all concerned have some definite idea of the relationship between the color and temperature of sparks.

Many observations have been made in laboratories under both natural and artificial light to determine this relationship. As a result of these observations such zones as the following may be established:

From 0 to 1000 deg. fahr. sparks are black. Occasionally at 1000 deg. there may be detected a faint red tint in the inner surface. The outer surface is black.

From 1100 to 1200 deg. sparks are faint or dull to slightly dark red.

From 1300 to 1400 deg. sparks are dark red with a frequent tendency to bright red at latter temperature.

From 1500 to 1600 deg. sparks are bright red. At the latter temperature a slight glow on the surface of the spark occasionally occurs.

From 1700 to 1900 deg. sparks are glowing red to glowing white. Many sparks when heated to 1800 and 1900 deg. will become enveloped in an intense short, white flame.

Due to the fact that sparks $^3/_{16}$ in. or $^1/_4$ in. in size cool very rapidly, it is a matter of a very few seconds after exposure to the atmosphere until there is a marked change in color. For instance, $^3/_{16}$-in. sparks heated to 1400 deg. fahr., and dropped on old shingles were black in less than three seconds; at 1700 deg., black in about four seconds; at 1900 deg., black in approximately seven seconds. When bright or glowing red they almost always became black on or before reaching the ground.

### Atmospheric Conditions

During the last few years much has been said about fire weather. Foresters are beginning to rely upon Weather Bureau reports as an indication of the likelihood of inception of

fires. The Weather Bureau now makes fire-weather forecasts which are highly regarded by foresters and others. The forecasts include information relating to:

Conditions actually causing fires, as storms accompanied by lightning;

Conditions favorable for inception of fires however caused, such as unusually low humidity and high temperature;

Conditions favorable to the spreading of small fires, such as hot winds and winds from moderate to high velocity.

These forecasts are undoubtedly helpful. However, they are not infallible. Moreover forecasts based upon general information covering a wide area may not be accurate for a particular locality because the topography and other influences may produce a condition of temperature, wind, precipitation, and humidity in restricted localities materially different from the broader area. Consequently the weather readings made at Spokane, Washington, for example, may be entirely different from actual conditions prevailing at Burke, Idaho, some thirty miles away, although included in the forecast area covered by the Bureau at Spokane. It would be possible to have high temperature, dryness, and no wind at Spokane, while at Burke, due to the marked differences in topography and elevation, the conditions would be entirely unlike those at Spokane. The Weather Bureau is recognizing this, and in important forest areas is correcting the situation by taking readings in many strategic places within these areas.

The moisture content of inflammables and the relative humidity of the atmosphere are also receiving marked attention in fire-prevention and control work. These factors are likewise creeping into litigation growing out of fires alleged to have been caused by locomotive sparks. They are undoubtedly important factors if correctly understood and applied. However, there seems to be some confusion in relation to these factors. Some seem to have the idea that low relative humidity necessarily indicates a state of inflammability. This is not true. There may be a low degree of relative humidity and at the same time a high moisture content of inflammables.

The moisture content of inflammables has much more to do with the likelihood of igniting such inflammables than existing relative humidity. Naturally moisture content is affected by relative humidity, but it does not change instantaneously with the change in humidity. Therefore relative humidity is not an accurate measure of the moisture content and hence of inflammability.

The Forest Service has made the following classifications by moisture content of the inflammability of duff, the matted pine needles and debris on forest floors:

| Moisture content, per cent | Degree of inflammability |
|---|---|
| 1 to $7^1/_2$ | Extreme |
| $7^1/_2$ to 10 | High |
| 10 to 14 | Medium |
| 14 to 18 | Very low |
| 18 to 26 | None |

This tabulation shows that duff must have a relatively low moisture content before it can be classified as highly inflammable. It also shows that by increasing the moisture content of duff from 10 to 26 per cent, the degree of inflammability passes from medium to a state of non-inflammability.

Experiments have been made with sparks $^3/_{16}$ in. in size to determine the effect of relative humidity. The tests were made with sparks ranging in temperature from 1400 to 1900 deg. fahr., with relative humidity varying from 35 to 60 per cent, and with wind ranging from zero to five miles per hour. Under these conditions the sparks were placed upon dry shingles. The results warrant the conclusion that relative humidity can be reduced from 60 to 25 per cent without any material effect upon the action of $^3/_{16}$-in. sparks, under constant conditions.

The general conclusion drawn from all the work thus far done as to the relationship between relative humidity and moisture content is that moisture content is a more reliable index to the degree of inflammability then relative humidity, and hence should be given greater credence in litigation.

### Character of Coal

The investigations, some of the results of which are herein indicated, have been made with cinders formed from various types of coal. In the last analysis a locomotive spark is largely carbon. Since the characteristics of carbon are approximately the same regardless of the coal from which it is formed, it is reasonable to expect the same kind of performance from all sparks. It is to be realized that the foregoing is a general broad statement and is not strictly scientifically true, but it is sufficiently accurate for all practical purposes. A test made with sparks from various types of coal substantiates the general statement. Tests have been made with sparks from low-grade and high-grade bituminous and anthracite coals, and approximately the same relative results were obtained with all sparks under the same set of conditions. It is a fair conclusion that under like atmospheric conditions and spark characteristics the behavior of sparks is approximately the same regardless of the character of the coal from which the sparks are derived.

Although tens of thousands of observations have been made while conducting locomotive road and laboratory tests, it is realized that sufficient data have not been accumulated from which to formulate any fixed laws relating to the behavior of locomotive sparks. However, these observations have so illuminated the subject as to warrant the conclusion that fundamental and incontrovertible laws may be laid down. Ways and means ought to be provided for intensifying on a large scale the scientific work that has been done and for widely disseminating the facts so derived. A procedure of this character would remove a great deal of public misinformation and prejudice, and contribute to the well-being of the railway companies.

In this connection a former member of a State Supreme Court, after being advised of the results of the investigations referred to, said, in substance: "The railroads should see to it that the great work which has been done is continued. It is scientifically demonstrated that the much reviled spark has generally had nothing to do in causing most of those fires alleged to have been started by locomotive sparks. If this scientific work is continued to its logical conclusion it would be accepted in court as prima facie evidence as are weather reports and therefore without the prerogative of the jury to pass arbitrary judgment."

## Discussion

H. G. Pinniger.[2] The writer agrees with the author that the railroads of America have in the past been forced to pay out large sums of money in settlement and to satisfy judgments for fire losses alleged to have been set out by locomotive sparks. Most defendants were satisfied that the fires originated from some other source, but due to lack of convincing proof the courts permitted juries to guess that the locomotive sparks would carry hundreds of feet beyond the railroad right of way and set up fires.

The writer's experience has been that the public at large through misinformation and prejudice has been responsible for charging such fires to locomotive sparks, and he is in accord with the author's statement that if this scientific work were once continued to its logical conclusion it would be accepted in court as

[2] District Claim Agent, Michigan Central Railroad Co., Detroit, Mich.

prima facie evidence, as are weather reports, and therefore do away with the prerogative of the jury to pass arbitrary judgment.

W. F. Every.[3] The statement from forestry sources that 12.8 per cent of all fires have their origin from the operation of railways is not readily accepted. Many large fires have their origin in places remote from permanent habitation and are too frequently charged as of railway origin through lack of close investigation to determine whether the fires reached the railway right of way by back fire, or were driven by high winds across the tracks.

However, the estimate of total annual cost by fires alleged to have been caused by locomotive sparks, placed at $12,000,000, is conservative, and doubtless low.

The claims presented against the railroads operating in Northern Minnesota growing out of what is commonly known as the Northern Minnesota forest fire of October 12, 1918, amounted to more than $50,000,000 and cost four railroads much more than the amount of $12,000,000 estimated as an annual cost to all railroads, notwithstanding the contention and fair showing of the railroads that the fire had its origin at several points far remote from the railway, and was destructive only because of a cyclonic wind on that date.

There is left no question as to the importance of pointing out the comparatively low danger from locomotive sparks. The general charge that a locomotive is a fire-setting agency had its beginning with the wood-burning engine, which emitted a spark entirely different from the present so-called spark from a coal-burning locomotive. The layman does not differentiate between a spark that is indeed a fire-carrying agency, and the cinder which retains only a small amount of heat sufficient to possess the fire color. The average laymen, before whom a railway must appear in defense of a charge of fire having been set by an engine, have no conception of the mechanical devices which prevent the escape of destructive material from the smokestack and ashpan. This wide general belief that a coal engine is a constant fire-setting agency is not surprising. It is common knowledge that sparks are emitted. Some fires are set. These are in highly inflammable material. As pointed out by the author, the other causes are not considered. The unknown causes are readily charged to locomotive sparks from failure to recognize other probable causes.

There is a great work to be done, worthy of much labor and expenditure of money, in the distribution of definite data already at hand, as furnished in the author's book on "Fire Losses—Locomotive Sparks."

It has been the writer's privilege to witness the intense interest displayed by courts, court attachés, juries, lawyers, and others in the testimony and demonstrations given by the author on data he has accumulated showing the low inflammability of sparks. In a great loss involving many people, and much sentiment and sympathy, the writer has seen these men and women spellbound—convinced. Furthermore, mechanical men are so clearly assisted by these actual experiments and data that new ways and means are sought to eliminate the escape of any cinder of size and heat sufficient to set fire.

It is but fair to say that only in recent years has the immense value of the research on this subject been appreciated, and, as suggested, the value of this enlightenment has been confined to a few localities. It is not generally known in its expert relation to the defense of law suits where railroad origin of fire is rightly denied.

[3] General Claim Agent, Northern Pacific Railway Co., St. Paul, Minn.

Stan D. Donnelly.[4] The writer has found this paper intensely interesting, particularly because he has occasionally been called upon to defend a suit for a railroad company in which it was claimed that a railroad locomotive had set fire to property.

Within the past year the writer's firm has defended the Chicago Great Western Railroad Company in a suit for damages in which the plaintiffs claimed that the railroad company was responsible for starting a fire resulting in the burning of certain buildings. The claim was that sparks thrown from the locomotive stack had set the fire, and very large damages were asked.

The case was tried in the United States District Court at St. Paul, Minn. If locomotive sparks had set the fire, they would have been required to travel through the air a distance of nearly 150 feet from the railroad right of way to the point where the fire started. One of the principal defenses in the case was that it was impossible for sparks to have been emitted from the smoke stack, traveled that distance, and set the fire. Upon this point the author testified on behalf of the defendant. He was permitted by the court to testify fully as to the behavior of locomotive sparks, his experiments with relation thereto, the results he obtained, and his conclusions. Just before the trial commenced he conducted an experiment which consisted of operating a train of the same railroad company under weather, wind, and grade conditions similar to those existing at the time and place the fire was alleged to have been set by the locomotive. He was permitted to give the results of that particular experiment. With his excellent help, it was possible to convince the jury that the fire was not and could not have been caused by sparks emitted from the stack of the locomotive as claimed by the plaintiff. The jury returned a verdict in favor of the defendant railroad company.

This jury was composed of farmers and business men, all men of considerable experience and of mature years. They apparently had no difficulty in agreeing with the author, notwithstanding the fact that the supreme-court decisions of many states, including Minnesota, have permitted verdicts to stand against railroad companies for large damages on account of fires occurring under circumstances and conditions similar to the claims of plaintiffs in this action.

It is the opinion of the writer and his associates that the author has been doing a great work, and that he is absolutely correct in his theories and conclusions on the subject of the behavior of locomotive sparks. Although very occasionally a passing railway locomotive may have started fires through emission of sparks from a stack (but more likely through coals falling from the firebox), the writer feels that heretofore railroad companies have been called upon to pay enormous sums of money on account of fires with which locomotive sparks had absolutely nothing to do.

T. W. Norcross.[5] In general, the conclusions of the Forest Service as to the distances from the track at which fire-starting sparks will fall are in rather close harmony with the conclusions of the author. It is believed that except for conditions of heavy grades and steep slopes, fireproofing of a railroad right of way for a horizontal distance of about 50 ft. on each side of a track is usually ample. The sparks which fall within 50 ft. horizontally from the center of the track include those which start forest fires, and and unless this area can be adequately fireproofed or the fire-starting sparks eliminated, the starting of forest fires will continue.

Very possibly locomotive sparks may not have been responsible

[4] Oppenheimer, Dickson, Hodgson, Brown, and Donnelly, Attorneys-at-Law. St. Paul, Minn.

[5] Chief Engineer, U. S. Department of Agriculture, Forest Service, Washington, D. C.

for forest fires in all cases where such sparks were given as the cause. No conclusive evidence, however, has been presented to support the statement quoted by the author that it has been "scientifically demonstrated that the much-reviled spark has generally had nothing to do in causing most of those fires alleged have been started by locomotive sparks."

It has been the experience of the Forest Service that much of the trouble experienced from sparks has been due to equipment that is out of order. Frequent and regular inspection to insure that spark-arresting devices are in standard condition has been found essential. Devices which do not readily get out of order are likewise important from this standpoint.

The nature of the material in which sparks fall is a matter of great importance. Dry shingles are not comparable to the dry, tinder-like grasses, dry leaves, and dry, rotten wood which are often found on rights of way which have not been cleaned. Rotten wood is now considered the most dangerous of all materials found on forest land.

William Elmer.[6] The effort made by our railroads to clean the ballast is tremendous. Those who are not in contact with the problem do not seem to appreciate the amount of money involved, especially where there is heavy traffic. Hundreds of men and thousands of dollars' worth of equipment are required, and the effort is enormous.

The amount of information which the writer has been able to obtain on the subject is but a portion of that which is in the possession of the maintenance man who started in that department and has followed it.

Perhaps the major reason for the source of trouble is the fouling from locomotive sparks. This can be noticed very clearly in cuts as against fills. The amount of leakage from coal cars of course does not vary whether the car is going through a cut or on a fill, but the amount of wind that can take away the sparks is greater on a fill than in a cut. The sparks fall more nearly vertical in the cut than on the fill.

In some instances, according to supervisors, the evidence indicates that on some parts of a railroad the locomotive sparks are the chief cause of fouling of the ballast.

In addition to the fire hazard the thought occurs to the writer that if something could be done to reduce locomotive sparks, there would result to the railroads themselves a saving of many dollars in the cleaning of ballast and in the cost of keeping the drainage conditions as they should be.

# Increasing the Production of Cotton Padders

By REYNOLDS LONGFIELD,[1] FAIRVIEW, N. J.

*When floor space becomes cramped and production throttled in certain departments of a growing business, the management is confronted with the task of enlarging capacity.*

*The author discloses the procedure followed in the dye house of a cotton-finishing plant for increasing production per man-hour and per machine-hour without investment for additional equipment.*

*He describes the psychological background and existing handicaps, and outlines methods of overcoming both with results of noteworthy improvements.*

EVERY cotton-goods finishing plant has, at rush times, experienced the annoying problem of putting a sufficient amount of material through one or more departments. In the course of changing business, no finishing plant or organization can be made like the "wonderful one-hoss shay"—a finished and homogeneous whole, perfectly balanced and all parts equally serviceable and functioning as planned.

Consequently, as the rush of business begins, the strength of the entire chain is measured by its weakest link. It is realized that there is a bottle-neck effect, and that work piles up in front of certain processes. Even then it is doubtful if the extent to which production on other operations is curtailed can be fully comprehended.

The usual old-fashioned method of overcoming such a condition is to enlarge the department by providing more floor space and placing additional equipment—frequently requiring large outlays of money. Spending money, unless warranted, is attempted suicide. One of the foremost principles advocated by the late Henry L. Gantt was to refrain from enlargement until maximum production was obtained with equipment in use, as determined by a thorough, scientific investigation.

In this paper a practical example is given showing certain conditions in one of the departments of a cotton-goods bleachery, how the problem was approached and worked out, and the results obtained.

It had been necessary to operate the direct-color padders considerably overtime during the busy season because of lack of space and equipment. The engineering department had included in its program a plan to study the operation of these machines for the purpose of determining what should be done. This work was started at once, hoping that methods might be developed whereby overtime at least could be entirely eliminated.

The foreman was of the old school—a good color man of considerable experience who took a personal pride in the appearance of his department, the quality of his work, and the welfare of his men. He had asked for task and bonus in his department, saying that he did not believe any increase in production possible, but that he was anxious for his men to receive pay on a par with the best-paid workers in the plant.

He was assured that the management would pay a bonus based on a task of what would be considered a fair day's work regardless of existing production, such task to be determined by means of a thorough and detailed analysis of operations. If these studies showed that, by means of mechanical applications or by different divisions of labor, increased production would result, he would be asked to install them.

To all this the foreman readily agreed, and investigations immediately started.

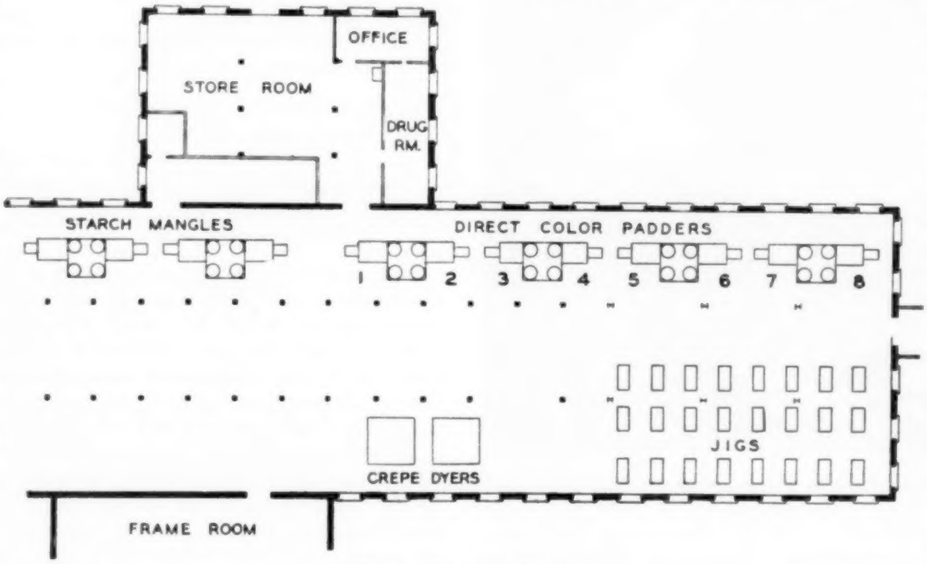

Fig. 1 Machine Layout

### Conditions As Found

The following will give a brief outline of conditions found in the department:

1 The material was received from the dry cans, plaited into box trucks of approximately 4000 yards each. The padders pulled directly from these boxes and delivered in 1000-yard rolls for drying.

2 The machine layout was good (Fig. 1), the padders being arranged in a good light on one side of the room, while the boxes containing work ahead were stored on the other side. Each machine was equipped with two 150-gallon tubs so that dye solution could be prepared in advance in one tub while the machine was drawing from the other.

3 The padders were so designed that when batching on a shell it was necessary, each time the machine was started, to give the shell a turn in order to overcome its inertia. The starting lever being on the entering side, the helper had to be on hand at the take-off side to give the roll the required twist when the operator was ready to start.

4 The organization, together with the duties of the various individuals briefly outlined, was:

| | |
|---|---|
| 1 Second hand | Supervising |
| 1 Drug man | Weighing out ingredients for dye bath |
| 2 Floor men | Supplying cloth as planned by foreman |
| 8 Operators | Running machines<br>Washing machines<br>Washing tubs |

[1] Industrial Engineer, Bellman Brook Bleachery.

Presented at the First National Meeting of the A.S.M.E. Textile Division, Boston, Mass., May 22, 1928.

8 Helpers........
- Getting dye solution
- Assisting in starting rolls
- Assisting in removing rolls
- Delivering complete work for drying
- Drying patches (or swatches) at tenter frames
- Taking patch for foreman's approval before proceeding with the dyeing of the lot.

### Analysis of Delays

After a brief survey, it appeared that the machines were producing at nearly full capacity, but considerable idleness of man time was evident. The real problem, however, was to increase production per machine-hour before considering output per man-hour. Consequently, care had to be exercised that man time should not be filled to the extent that poor service would result

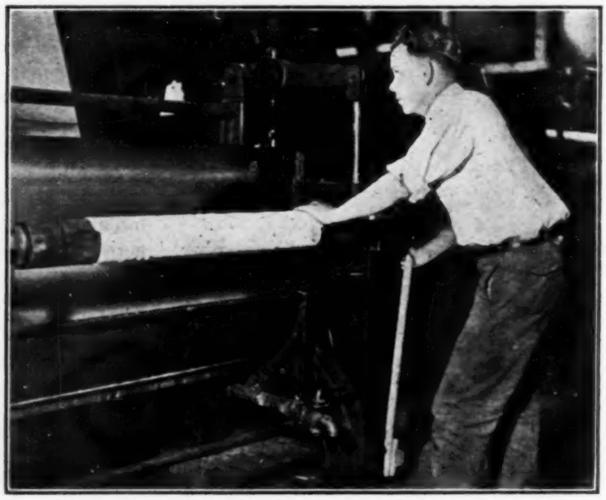

Fig. 2 Starting Machine From Delivery Side Without Assistance

in machine delays. Accordingly idleness was considered in two groups:

Group I. Machine delays, the elimination of which would increase production per machine-hour; and

Group II. Idle man time, the elimination of which would increase output per man-hour.

Under Group I, machine delays were listed as follows:

1. Incorrect speeds of machines. No two machines were running at the same speed, although a definite speed had been established for each class of goods.
2. Washing the tub. The operator did this, permitting the machine to stand idle while doing so. If another were designated to wash the tub while the machine was still in operation, the time thus saved would mean more yards by the end of the day.
3. Waiting for the dye solution on every shade. This resulted because the helper always delivered the final roll before obtaining the color for the next shade.
4. Patches were dried at the tenter frame. The walk there and back required a great deal of time, considering that there were a hundred or more patches each day. A patch drier would eliminate this.
5. Miscellaneous delays resulting from lack of interest in the work were frequent. It was believed that a wage incentive would minimize these.

Under Group II, in the analysis of idle man time, it was found that the delays were numerous, variable in length, and difficult to classify. One man frequently waiting for another indicated poor distribution of labor and lack of co-operation.

### Developing Plans

In view of this, it was decided to classify the duties rather than the idleness of each man, and to plan a new distribution of labor to a new type of organization. The padder being the basis of work, the operation should center around it. The principal duty of the operator should be to keep it producing, machine delays as classified in Group I being avoided. Then, in order that the operator might work efficiently, all idle time had to be eliminated and a full-time job laid out for him. To do this, conditions had to be such as to make him as independent of the rest of the organization as possible. Those supplying the machine with materials had to do so in sufficient time to permit him to have all material when wanted; and all joint operations which required the assistance of others had to be altered so that they might be performed singly.

The following duties were those wherein he was jointly or entirely dependent upon others:

1. Supplying of goods to be dyed
2. Supplying the dye solution
3. Delivering the finished work for drying
4. Drying the patch and having it approved
5. Starting a roll
6. Removing a finished roll.

For the first three of these, the operator was entirely dependent upon others; but with good supply men and truckers the work could be planned so that there would be no delays.

Fourth, drying the patch and having it approved had always been done by the helper, while the operator, with nothing else to do, sat down and waited for the foreman's authorization to proceed. There was no doubt that the more responsible operator would do it more quickly if this were required of him.

Fifth, the helper always assisted in starting the roll because the starting lever was on the entering side of the machine and it was necessary for some one to be on the take-off side to give the roll momentum. The solution was simple. It was only necessary to put an additional starting lever on the take-off side, so that the operator had but to start the next roll from the same position as where he had removed the last (see Fig. 2).

Sixth, removing the roll. A thousand yards of wet cloth in a roll was heavy, and it seemed that assistance here would be necessary. The machine was so constructed that if the roll were not removed carefully, it would hit the side and fall to the floor. The aisle did not permit room for extension arms and the problem was annoying. Finally, the idea was conceived of placing a mechanical hand in the form of a support to hold one end of the center bar while the other end could be swung slowly and carefully out over the aisle and the roll thus lowered to the truck and there left for the trucker to deliver for drying.

Accordingly all plans were laid to operate the padder without a helper. Four of his duties were to be performed by the operator: namely, drying patches, having patches approved, starting a new roll, and removing the finished roll. There remained the supplying of dye solution and the delivering of finished rolls for drying. It was evident that not only were helpers not needed, but that their remaining duties should fall into two distinct jobs, trucking and supplying dye solution; and to these should be added that of washing the tubs.

This in general took care of the principal operations, but a number of minor details had to be worked out, such as the making of roll tags, labeling of buckets, adding of steam pipes, and labeling

of the same to prevent confusion. Each of the smallest details was noted and given its place in the organization so that there would be no chance of any two conflicting. Finally, it was confidently felt that nothing had been overlooked and that the scheme was correct.

After the type of organization was planned it was necessary to determine the number of men required for each of the several operations. Since this had to be done accurately, scientific time studies were made. However, after the careful analysis that had already been completed, very few time studies were necessary; a very definite idea had been reached as to the number of men needed, and it but remained to check all plans.

The organization then appeared on paper as follows:

1 Second hand
1 Drug man
1 Floor man
1 Trucker
1 Color man
1 Cleaning man
7 Operators.

This arrangement would release,

1 Floor man
5 Helpers
1 Operator.

These transferred to other departments one at a time and the remainder paid a bonus of 20 per cent would call for the following results:

Increased machine capacity, 20 per cent
Reduction in working force, 35 per cent
Increase in pay to men, 20 per cent.

### Selling the Plan

As to this point, all plans were based entirely on observation. They were strictly plans of an official observer, having been developed in about a month's time on the job. But, of course, it is one thing to plan such changes and another to put them into effect with as little upset to the organization as possible. It was well realized that the greatest caution would be required to maintain the morale of the men.

The best feeling existed at the time, however, and skepticism had practically disappeared. Nothing definite had been discussed with the foreman because there had been nothing definite to offer. The men realized that the intention was to increase their pay, and that such increase would be based upon the amount of work produced. The older and more serious minded welcomed the idea. Only those who habitually soldiered were annoyed, but their attitude carried no weight with their fellow-men. It was felt that the proper attitude had been developed in the department, and that all plans were well laid.

Then one day the foreman was invited into the office for the purpose of discussing the work as laid out for the padders. The scheme was briefly outlined and he was told in as few words as possible the method of proposed procedure—that the machines would be equipped with two or three mechanical appliances in order that the operator could work independently of others, that an extra man would wash all tubs for the machine operators in order to increase running time, and that the operator would deliver his own patches for approval rather than sit down and wait for the helper to do it for him. He grasped the idea immediately and proceeded to ask questions concerning the minor details. The problem had been thoroughly worked out and he was given the answer to every question; but it was evident he had not been convinced. He had confidence in his organization and was reluctant to make any change. He was fearful that production would be curtailed rather than assisted, and that demoralization would result. To convince him that there would be no chance of disrupting the organization, he was told that the operation as planned would be worked out on one machine and later extended to the others.

### Installation

With this method of procedure agreed upon, one machine was selected. The operator was a husky Italian of middle age, father of seven children, and a worker rather independent of the rest. His term of service was not as long as most of the others, making it probable that he would be more adaptable. He was told that a bonus had been worked out for the job, but that before it could be paid alterations would be necessary both on the machine and the operation itself.

He accepted this with an open mind. It was known throughout the department why these investigations had been made, and that such work had been going on in another department where men had increased their pay 10 to 15 cents per hour. Therefore, if the opportunity were offered him, he would be anxious to try—"provided," he interposed, "it would not be necessary to work too hard."

The mechanical department started immediately to equip the machines according to instructions and drawings which had been prepared in advance. The illumination was improved, a better type of yardage clock installed, and the extra starting lever placed on the take-off side of the machine without having any noticeable effect upon the attitude of the employees. But when the one-man take-off neared completion, the various operators became appreciably annoyed. The man upon whose machine the work was in progress protested. One thousand yards of wet cloth were heavy and all that *two* men could handle—it was entirely out of the question for one man to handle a roll without assistance. He was good-naturedly humored and advised to wait and see how it worked.

Finally everything was in readiness. No change in methods had been requested, for it was evident that, first, the minds of the various men should be put at ease with reference to removing the rolls. The machine was supplied with dye solution and material, and started up as usual. At the completion of the first roll, all members of the department, including the foreman, curious as to the outcome, gathered around to see the result of the demonstration.

The designer of the apparatus, a member of the engineering department and a man of slight stature weighing about 140 pounds, stepped forward and grasped the center bar. With one hand he swung the roll from the machine and to the truck with no apparent effort. It was now easier for one man than it had been for two prior to the changes (see Figs. 3 and 4). The operator, a big 180-pound Italian, grinned sheepishly and returned to his work. For a long time afterward he would permit no one else to remove the roll, always insisting upon performing the operation himself.

The machine was now equipped to permit the elimination of idle man time. These contrivances were applied first, that the operators might have ample time to get used to them, and to some extent they were immediately adopted, although no requests had been made, it being necessary to do away with machine delays first. Accordingly, the machine delays were taken up in the following order:

1 All materials were classified and the correct speed for each class of goods determined. The starting box on each machine was then marked to show where the switch should be located for the proper speed, and the foreman was required to designate the class of all goods delivered.

2 The tub was washed by an extra man whose duty it was to

come immediately on signal from the operator when the last of the dye solution had been drawn.

3 Dye solution was prepared in advance and the helper's principal job was to see that it was in the tub before the operator was ready for it.

4 A patch drier was built. This was an elaborate affair with controls on heat, draft, and circulation permitting an exact duplication of conditions on the tenter frames. The foreman not only approved but became quite enthusiastic over its operation. The walk to and from the tenter frames was not only eliminated but the actual time of drying the patch was cut in half.

5 Miscellaneous delays were then approached through personal attention. The foreman was asked to require the drug man and floor men to give this machine the best of service. Each delay was noted and approached from its own particular angle, until there remained only the wage incentive to do the rest.

After devoting a few days to perfecting the service and reducing all machine delays to a minimum, it could be seen that the idle man time also was affected. The operator in the absence of his helper had learned not to wait. He had found it just as easy to start the roll, run a thousand yards, and remove it without assistance, sometimes even with the helper standing by and watching. However, when the patch was taken to be dried and then carried to the office for approval, the operator always found a nice, soft place to sit down and wait. The foreman had been asked to change this policy and require the operator to make this trip to the office for the purpose of getting closer contact and receiving all instructions at first hand. But the foreman considered it inadvisable in view of the fact that it had always been the method in the plant, and that he had never seen it done otherwise. Nevertheless there was no other solution, and in order to maintain equanimity it was necessary to

Fig. 3 Doffing a Roll Under Original Conditions, Two Men Required

approach the problem from another angle—that of dollars and cents.

### The Wage Incentive

The wage-incentive plan in effect in the plant was the regular Gantt task-and-bonus, allotting a definite time for a job. If accomplished in the time allowed, or less, the man's hourly rate was increased and he was paid for the full time allowed.

On the padders, this worked out simply. The task allowed was 0.2 hour per 1000 yards, and 0.2 hour for each patch. The man's hourly rate was 50 cents. A bonus of 20 per cent then amounted to 10 cents, giving a total wage of 60 cents per hour for accomplishing task.

With these figures it was simple to explain to the operator that he was to be paid 12 cents for each 1000-yard roll produced and 12 cents for each patch submitted, provided that he maintained an average of five rolls and patches per hour while on bonus.

It is always easier to explain it in some such easy way at the start, but invariably the average employee learns the regular method of calculating bonus in a short time.

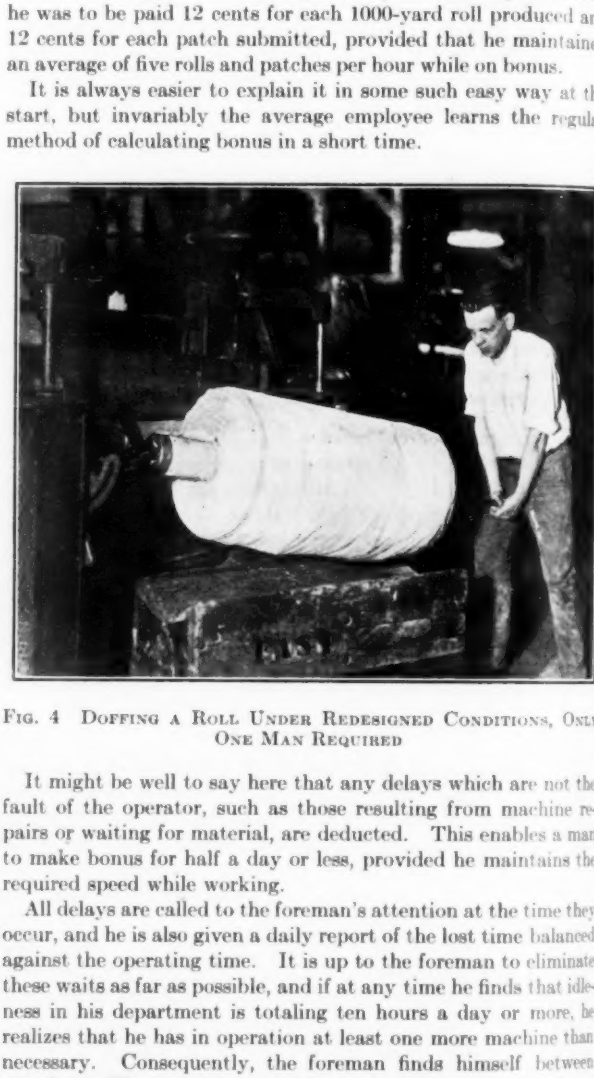

Fig. 4 Doffing a Roll Under Redesigned Conditions, Only One Man Required

It might be well to say here that any delays which are not the fault of the operator, such as those resulting from machine repairs or waiting for material, are deducted. This enables a man to make bonus for half a day or less, provided he maintains the required speed while working.

All delays are called to the foreman's attention at the time they occur, and he is also given a daily report of the lost time balanced against the operating time. It is up to the foreman to eliminate these waits as far as possible, and if at any time he finds that idleness in his department is totaling ten hours a day or more, he realizes that he has in operation at least one more machine than necessary. Consequently, the foreman finds himself between two fires. The operative, realizing that delays may cause him to lose bonus if no deduction is made, seeks credit for each wait. On the other hand, the foreman, subject to criticism from the management for excessive idleness, must maintain conditions to eliminate these waits.

In a department not working on such a plan, it is impossible to get a correct record of either machine- or man-hour delays.

### Starting the Task

On the day that the task was to be started, the operator on the experimental machine was approached before starting in the morning. He knew the general task-and-bonus plan, having talked with men from other departments who had been increasing their daily wage. He did not know how hard this particular task was, but he was anxious to receive more money and was willing to try. When told that he would be expected to dry his own patches and take them to the office for approval, he asked what the helper would be doing. It was explained that at present there was nothing, but since the operator was to receive the bonus, he should dry the patches. The result was not sur-

prising, for the handwriting on the wall was plain—in fact, rumors had been current for some time that some helpers would not be needed—the man parried and sidestepped. He argued that the operator had never dried the patch before; why, now, should he start it? It would add considerable work, and besides others would criticize. He was told that the management paid bonus on work done and it would be out of the question for him to expect bonus on idle time, but all to no avail. He seemed immovable, apparently affected by what others would think. The man was of the type that did not care for the opinions of others as a rule; but this seemed like asking too much and it was decided to lay off for a time. However, it was still believed that an entering wedge could be driven through the pocketbook, for he had a large family and needed all extra money possible to get. In order not to embarrass him and yet give him the chance to see that the task was fair and the bonus liberal, it was agreed that temporarily he need not dry the patch, but the time he waited for the helper to do it for him would be considered as idle time. Should he decide to carry the patch, he was assured that he would receive credit for it each time that he did.

The scheme worked as planned. At the start, he earned between 80 cents and a dollar a day extra. Soon he began experimenting, first to see how much he could earn, and then to see how easy he could work and still receive bonus. He dried a few patches and then a few more. Finally it dawned upon him that he was letting 20 or 25 cents a day slip through his fingers. Before two weeks had passed he was doing the task as laid out, and apparently without criticism from others. By this time several had asked for bonus, and one had gone so far as to dry all his patches to show willingness to do as requested.

The morale in the department was not at its best, but it was vastly improved and was considered satisfactory. Task and bonus had been applied on one machine for three weeks and had worked out to the satisfaction of one man. Others wanted it, so it was decided to go ahead with the work, and the mechanical department was given orders to equip all machines. As fast as they were put into shape the operators were offered bonus, and by the end of the week all machines were performing the task.

The work of improvement had gone surprisingly fast in view of the fact that more obstacles had been encountered than were expected. It had been planned to have the operation running smoothly by the time the peak load was reached, that production might not be limited; and this had practically been accomplished. Now, with the busy season at hand, all operators were working under the new conditions and the padders were not only producing the same number of yards as in the previous year with one less machine and without overtime, but upon an examination of reports for over a year previous it was found that a record week of production had been completed.

### Eliminating Excess Men

Although the bulk of the work had been finished, there was considerable yet to be done. Results so far had been obtained by keeping the machines in operation with little attention to idle man time. True, the operators had been given full-time jobs, but this had been accomplished by appropriating duties of the helpers, thus exaggerating their condition and leaving them but little to do. The two floor men also were finding it difficult to look busy, their principal work being to keep lots straight.

Accordingly one floor man and five helpers were transferred to other parts of the mill, retaining the senior floor man and three most likely helpers with duties apportioned as follows:

Floor man, to supply goods in proper order
Color man, to supply the dye solution
Trucker, to supply shells and deliver rolls for drying
Cleaning man, to wash tubs and assist others where possible.

For performing these duties satisfactorily, they were each to receive 15 per cent of the total bonus paid to the operators. If an operator lost bonus, the bonus paid to the service men automatically became proportionately smaller. This plan was used to develop a spirit of cooperation. Becoming vitally interested in the production of the machines, they not only did everything to help the operators, but helped each other as well.

### Breaking in a New Machine

Finally the new type of organization with the new distribution of labor was in operation as planned—not yet a perfect running machine but a well-designed one. All machines had to be broken into use gradually no matter how well put together, and this one did not prove the exception; it still needed the rough edges worn off. And in addition to being worn in, it had to be equipped with meters and gages in order to check the performance at all times and record bad conditions.

Although the organization was doing good work, each and every man, including the foreman, was on a job entirely different from the one at which he had served for years. Machine delays were entirely too frequent. The color man was frequently late in delivering the dye solution, and the floor man had difficulty at times in getting the next lot. They had not learned the best way of handling their work. Time would have improved this, but best results would never have been obtained without proper records and control.

To furnish these, a daily report was drawn up for the foreman, giving the record of each man as to work done, bonus earned, of idle time and why. When these reports first began to appear the foreman could not believe that such idleness was actually occurring, and made it a point to check each and every one. Finally becoming convinced that his department was totaling more than ten hours a day of machine idleness, he realized that he was operating with more machines than were necessary. On short notice he cut off one machine and made a drive on the service men to eliminate all delays.

### Results

Here the department is left with the feeling that it is in first-class condition, although not a finished product, for a year's operation at least will be required before conditions and operations are running as smoothly as desired. And always the engineer will receive the same daily report which the foreman receives, that he may know if conditions are improving or retrograding.

Here, a brief survey of records is opportune in order to determine, by comparing data obtained prior to the change with that of the new organization, if results have come up to expectations.

| | | |
|---|---|---|
| Average daily production per machine: | Prior | 20,100 yards |
| | Present | 27,500 yards |
| | Increase | 36 per cent |
| Average daily wage per man: | Prior | $4.55 |
| | Present | $5.70 |
| | Increase | 25 per cent |
| Average unit labor cost: | Prior | $0.072 |
| | Present | $0.052 |
| | Decrease | $27\frac{1}{2}$ per cent |

Annual reduction in labor cost per 100,000,000 yards—$20,000.

Also, it would be interesting to note conditions pertinent to the quality of performance. Maintenance of quality is strictly a function of the foreman, and the following conditions afford him greater opportunities to this end:

1 The best men were retained when the excess help was transferred

2 Competitive concerns must raise their bids considerably in order to entice the skilled help
3 A higher grade of employee is being obtained because of the higher wage
4 Operators watch their work more closely in order to avoid difficulties
5 There is less distraction in the absence of men with nothing to do.

The data presented here to show results in connection with quantity and quality production, together with increased capacity and lowered costs, are very conservative. As time goes by and wrinkles are further smoothed out, the figures will appear even more favorable.

### Conclusion

The problem has not been that of a dye house alone, but is typical of what occurs in many departments in every finishing plant. However, an organization of this type, where the duties of its various members are functional and its success depends strictly upon cooperation, seemed particularly applicable in this case. It is not recommended for all dyeing departments, for conditions vary widely throughout the textile industry, but an average set of conditions found in an average department has been cited.

But when conditions are cramped, and flow of work is throttled, and costs are high, or capacity is limited, unless the department has been thoroughly analyzed by one who has the time and experience, there is every reason to believe the company is throwing away money. If the stage has been reached where the purchase of new equipment or more floor space seems necessary, it is strongly recommended that a scientific investigation be made before laying out the money.

## Discussion

T. R. Read.[2] We recognize the truth of what we have just heard, having put a bonus system in three of our branches on padders, and I would like to say that there is hardly an operation in a finishing plant that does not offer an almost equally interesting story.

We have of course found differences of opinion as to the best method of handling cloth through the padders and also as to the best means of taking patches, and while we have arrived at definite opinion as to the most efficient way of handling these, nevertheless we sometimes have to concede some of the smaller points for the sake of not interfering with the boss dyer's own ideal of best quality.

I can see that our story is very similar to the author's. I think the only difference is one of cost (a very slight difference) and a different wage-incentive system. We are using a modified Gantt bonus system.

### Author's Closure

Gerald Chapin of the Pacific Mills, Lawrence, Mass., asked the size of the runs on which was obtained the figure showing an average of 27,500 yd. a day for each machine. The actual average is a little higher than 2000 yd. per shade, probably running nearer to 2200 yd. A very important part of the same question is, how many strike-offs does the operator take before hitting a match to the shade? Figures show about 50 per cent more strike-offs than shades. In other words, this means that every second shade the foreman hits a match at the first attempt. Of course what brings up the average is the running of samples, etc., which require more strike-offs than the regular runs. Here is some data which may give more clearly the possible production under actual conditions. I do not know that these figures are of a record day, but they are of a very good day and will show what these particular machines are doing and what may be expected from machines working under bonus conditions. The average per machine for the day was 35,500 yd., with 13 shades and 20 strike-offs per machine, netting the operators an average bonus of $1.46. This shows an average of 2700 yd. per shade, with approximately 54 per cent more strike-offs than shades.

J. D. Robertson, Mount Hope Finishing Co., North Dighton, Mass., asked what percentage of time the machines were actually running, that is, the percentage of running time that the cloth was actually passing through the machine. Mr. Robertson had been trying some service recorders like those in use on automobile trucks and found on the padders that he was getting an average of 60 per cent running time. Answering Mr. Robertson, without any specific data I should say about 60 per cent is correct, or a little more than the time spent in taking strike-offs. This can be figured quite accurately for any particular time knowing the number of patches taken and the number of yards delivered. The time permitted by the task for taking a strike-off is equal to the time for running 1000 yd. Upon the day just mentioned seven hours were allowed for running 35,000 yd. and four hours for taking 20 patches. This shows a running time of seven-elevenths of a day's work, equivalent to a little more than 63 per cent.

In reference to the patch drier, this was developed carefully and thoroughly, for the foreman was very particular about the treatment his patches received. He would not consider the ordinary steam-heated cylinder because of the possibility of the metal affecting the shade. Even if the patch was placed between two pieces of cloth to prevent it from coming into contact with the metal, the heat seemed excessive and fear was expressed that the correct shade would not be obtained. So the patch drier was built to duplicate conditions on the frames. This was a well-insulated box containing eight drawers, one for each padder. Under the drawers was a steam coil fed by live steam which could be throttled to obtain proper heating and exhausting into a steam trap. A Western Electric fan with three speeds enabled the control of air circulated through the steam coils and down over the patches which were placed into the drawers with wire-net bottoms. A small damper at the bottom of the box to allow fresh air to enter and another at the top to permit stale air to escape enabled the foreman to regulate the moisture content until he was satisfied that conditions were maintained as constant and satisfactory. Better results were thus obtained than previously when drying patches at the frames. Formerly when the operator took the patch for drying he did not carry it into the hot house, but held it close to the opening at the entering end to be dried by the air thus escaping. This air was not only moisture-laden, but had lost considerable heat.

Answering the question of our chairman, Henry M. Burke, we did not use pumps to return the dye solution to the tubs. Pumps used for this purpose make a good labor-saving device, but under this particular condition would not have resulted in time saving. There was never more than a bucket and a half or two buckets of dye solution in the machine for taking a strike-off. If the patch was not accepted, it was necessary to wait for the color man to supply the additional dyestuff, requiring approximately a minute and a half. During this interim the operator had ample time to drain the machine and return the solution to the tub. He also had time to sew a new leader to the patch, preparatory for the next strike-off. Pumps would not affect the efficiency of the operation.

# The Value of Water in Textile Mills for Purposes Other Than Water Power

By CHARLES T. MAIN,[1] BOSTON, MASS.

*The value of water for industrial purposes—process water, water for condensers, etc.—is an item which must be included in the valuation of many industrial properties. The object of the paper is not so much to establish definite values as to discuss methods which will assist in arriving at definite figures for any particular case. In his analysis the author discusses four cases and various conditions which affect them: (1) Where water is purchased from a water-power company; (2) where it is taken from a stream on which the user owns the riparian rights; (3) where it is obtained from driven wells; and (4) where it is purchased from a town or city supply. An example of the use of the basic figures arrived at by the author is given for the case of a colored woolen mill.*

THE value of water for industrial purposes is an item which must be included in the valuations of many industrial properties.

Many industries are dependent upon an ample supply for their processes, and when takings of watershed for public water supplies are made, enough suitable water must be left to carry on the processes requiring its use. If this is not done, it may be necessary to condemn the whole property.

The author has not seen any printed matter on this subject, and, with the hope of bringing out some valuable information, is presenting some views on the subject which may establish a starting point at least for some logical conclusions.

The object of this paper is not to establish definite values so much as to discuss methods which will assist in arriving at definite figures representing or indicating values in any particular case.

The figures given are approximate only, and cannot be expected to apply to every case. If the paper serves to bring out discussion on this subject, its object will have been partially accomplished.

The determination of the value of water for power can be made with some degree of accuracy, but the determination of the value of water, or the right to use water for the various processes in manufacturing, and for other purposes, as condensing, and for what might be called domestic uses in the mill, is difficult, because of the wide range of the cost of procuring a suitable supply and the varying conditions of its uses.

The value of anything is not necessarily measured by what it costs to obtain it, but by what it would cost to obtain the same or equivalent results in a reasonable and practicable way.

Thus the value of a water power can be determined by comparing the cost of producing and delivering power to the place where it is used with the cost of producing and delivering the same amount of equally reliable power in some other way, as by steam power, internal-combustion engines, or by purchased electric current, taking into account in each case all the elements of cost.

There is no substitute at present for water for manufacturing purposes, and therefore its value cannot be determined by the substitution of some other thing which would produce the same results.

There have been sales of properties in which one element of value is the possibility of using water for manufacturing purposes, but it is impossible to segregate the value of this element from all other elements of value.

The value of water, or the right to draw water, depends largely upon the use to which it is to be put, and the physical requirements for preparing it for such use.

In a manufacturing plant there are usually the following uses, in addition to the use of water for water power:

1 Water for manufacturing purposes, sometimes called process water
2 Water for condensing when steam power is produced and where there is only a partial or no use for low-pressure steam for heating or in the manufacturing processes
3 Water for sanitary or domestic purposes
4 Water for drinking.

As a usual thing, drinking water is obtained from a different source from that which supplies the water for the other uses, and as the amount of water required for sanitary purposes is relatively small compared with amount of process and condensing water, these two uses will be given no further consideration here.

### Water for Manufacturing Purposes

Occasionally a concern has an ample supply of water which is particularly adapted in softness and other qualities to the work to be done. In such a case the water for manufacturing may have a special value.

Such a condition may occur in a small stream which is unpolluted by any other manufacturing plant above it on the stream, and which can be reservoired, or on any stream where the pollution or hardness is so small as not to be harmful.

In a few instances there are reservoirs furnishing by gravity an ample supply of good water which comes from a source independent of the main stream.

The cost of procuring such a supply would usually be the cost of creating the reservoir by the purchase of some cheap land and the construction of a dam, and of the piping system to the mill. The cost of such plants will vary considerably.

There are some cases in which the process water is supplied from driven or dug wells. The cost of such wells, and the amount of water available, will vary enormously. With such an arrangement there is the cost of pumping.

These physical structures add to the value of a plant whatever they cost, less depreciation, up to a point where the fixed and operating charges become equal to the cost of obtaining water in some other ordinary and customary way. Above that point there is no further value to be added for physical structures and nothing left for the value of the water itself, just as in the case of water for power, where, when the cost of physical structures reaches a certain amount, anything above that amount is of no value, and there is nothing left for the value of the privilege.

In manufacturing cities where the water is controlled by a separate water-power company, water is sold, or leased, for power and other purposes, and in such cases the sale price is some measure of the value of the water.

Most of the indentures for water were made many years ago, and were largely made for water for power and do not represent

[1] Pres., Chas. T. Main, Inc., Engineers. Past-President A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Textile Division, Boston, Mass., May 22, 1928.

present-day values of water for manufacturing purposes. More recent leases are some indication of present values. At least they show what some manufacturers are paying for this service.

In the great majority of cases the mill owns the riparian rights on a stream and takes its water from the same pond from which water is drawn for power. If the level of the water above the dam is of sufficient elevation, the water can be drawn by gravity into the various machines in which it is used. If the water level is not sufficiently high, the water must be pumped.

Most of the earlier textile mills, especially the woolen mills, were located in New England on rivers, the waters of which were unpolluted and were suitable for manufacturing purposes.

As the number of mills and communities have increased, these rivers have become more or less polluted, and the water from some of them must be treated before it can be used. The value of the supply under these conditions is relatively less than it was formerly. In some cases the supply has been abandoned, and water purchased. This may be a burden which tends to decrease the value of the property.

The use of water from city or town supplies at domestic rates would be prohibitive in most cases, especially if the amount used is large.

As the number of new and good supplies available has diminished, the value of the remaining good supplies has increased.

The value of the right to draw and use water for manufacturing purposes is not necessarily measured by the cost of getting it. It can be measured by the cost of getting it in some reasonable and common method. As in the case of water power, the less the physical structures cost to build and maintain, the more valuable is the privilege or right to draw. There is a reasonable sum that can be spent for the privilege and plant so that the concern will not be handicapped in competition with other mills.

For example, supposing the water is obtained from deep wells at great relative cost, nothing could be added to the value of the site for this when compared with the value of sites where the cost of getting water would be comparatively low; or, if the water is taken from the town or city supply at high rates, no value can be added to the site for this reason; but on the other hand there may be something to be deducted for this handicap, in the same way that a location requiring excessive haulage will involve a constant source of extra expense which tends to reduce the value of the site.

The cost of obtaining water for manufacturing purposes may be an indication of its value under any of the following conditions:

1 When the water is purchased from a water-power company. This gives the most definite indication and applies to many cases of concerns engaged in similar businesses.

2 When the water is taken from a stream by the owner of the property who also owns the riparian rights, accomplished by the building of the necessary structures and appliances to make use of the water. This is the most common case, and is usually the least expensive method of obtaining the water.

3 When the water is obtained from wells which usually involves large expenditures for construction and operation. This is not a common method and usually results in a higher cost of water and, therefore, a lower additional value for the site than with (1) or (2).

4 When water must be purchased from a public or privately owned water supply principally used for some other purpose, such as the supply for a town or city. The costs in this case are usually prohibitive for plants requiring large amounts of water.

### Water Obtained From Water-Power Companies

Water is sold or leased by water-power companies as in Lawrence, Lowell, and Holyoke, but even in these places the charges are not uniform. Some of the sales of water for manufacturing and condensing made prior to the period of increased cost of the last few years, which are not confused with water for power, indicate that a fair charge, at the time, for such water was about $1200 a year a mill power, a mill power being equivalent to about 8,000,000 gal. in 10 hours.

This charge was before the increase in cost of about everything and the decreased value of the dollar, and under present conditions may be equivalent to about $3000 a year.

In a more recent agreement the price for 8,000,000 gal. a day was fixed as follows:

| | | |
|---|---|---|
| First 5,000,000 gal. at $3.00 per million | = | $15.00 |
| Next 3,000,000 gal. at $2.00 per million | = | 6.00 |
| | | $21.00 |

$21 × 300 days = $6300 a year for 8,000,000 gal. a day, or about $800 a year for a million gallons a day.

In these cases the water-power companies own, control, and operate the dam and canals up to the intake for the water into the mill, the mill having only the local distribution system to install and maintain. The mill may also have filter and pumping plants for a portion, or all, of the water. This water is usually supplied under some head, and a good deal of it may be used without pumping.

### Water Taken From a River

The most common method is where the water is taken from a river on which the user owns the riparian rights, and which is drawn by gravity, or where it is pumped to tanks and used from the tanks by gravity.

In many of these cases water is furnished under some head and much of it could be used without pumping. The conditions are generally not much different from those when water is taken from a water-power company, except that the right to the use of the water is a part of the riparian rights of the owner of the property, the water itself does not have to be paid for, and the dam, canals, or other channels are owned and maintained by the mill itself. Usually the development is made primarily for water power, and the water for manufacturing purposes taken from the pond created for power purposes.

The cost of obtaining water in this way is relatively small in most cases. Its value would be no more than water of similar quality supplied under similar conditions in the large manufacturing centers by the water-power companies.

### Driven Wells

The cost of driven wells will vary enormously. With an adequate supply of water at a short distance below the surface, the cost might be such as to compare fairly with the cost of obtaining water from a river or from a water-power company. With deep-driven wells the cost would be so high as to be a burden on the mill in comparison with the other methods of obtaining water.

A recent installation for 2,000,000 gal. a day cost $48,560. If this plant were extended to a capacity of 8,000,000 gal., the installation cost would be not over $150,000 or about $19,000 per million gallons per day.

### Purchase of Town or City Water

It is not the usual custom to encourage the use of water from town or city supplies by manufacturing plants using large quantities of water. Most towns and cities would be unable to supply the amount required by large mills.

The town or city must charge enough for this water, if it does sell it, to cover the cost of obtaining, and usually of pumping, storing, and distributing the water, and for such treatment

as may be given to it. The water would be delivered at a greater head than is required if the water is pumped from the river into tanks. All of these charges would make a price for the water that would probably be prohibitive. If, however, there should be one or more acceptable establishments requiring considerable amounts of water in a town, and if the supply is ample, the charge should be the minimum possible amount, even perhaps at less than cost, in order to encourage the establishments to remain there for the general good of the community.

### Summary of Cost

1—*Water Obtained From Water-Power Companies.* A rental of \$3000 per year for the right to draw 8,000,000 gal. a day is equal to \$375 a year per million gallons a day.

As the water-power company maintains the dam and water channels, the user has only the distribution system on his property to maintain, the expense of which is common to all users. The yearly cost might then be capitalized at interest charges only, say, 6 per cent.

The amount \$375 capitalized at 6 per cent is equal to about \$6000. This represents the capital value of the right to draw 1,000,000 gal. a day for the working days of the year, and is low in comparison with a more recent lease.

Based on the agreement of \$21 a day for 8,000,000 gal., which is equivalent to about \$800 a year for a million gallons a day, we have \$800 capitalized at 6 per cent, equal to about \$13,000 for the value of the right to draw one million gallon per day.

At a rate of \$3 a day per million gallons this would be \$15,000.

2—*Water Obtained From Owner's Pond.* A million gallons in ten hours = 3.7 cu. ft. per sec. With an assumed head of 30 ft., this would produce about 10 hp. This might be worth for power \$20 a year per hp., or about \$200 a year in all. This amount capitalized at 6 per cent equals \$3333.

The value for manufacturing purposes is greater than for power, and therefore this figure is low.

3—*Water From Driven Wells.* In one case we have an installation cost of \$19,000 per million gallons a day. This is high in comparison with the other methods.

*Arbitrary Assumption.* We have now figured a range from \$6000 to \$19,000 as the capital value per million gallons a day. It might be safe to set up an arbitrary base value of \$10,000 from which to start.

It might also be assumed as a general proposition that one-third of the water, which is the amount used for the final process work, requires pumping and filtering, a supply which requires no treatment or pumping is worth considerably more than the base of \$10,000 per million gallons a day.

### Effect on Value by Reason of Not Being Obliged to Pump

If all of the water is pumped, with a total lift and head of 30 ft., the cost of pumping will be about 0.5 cent per 1000 gal., or \$5 per million gallons a day, or \$1500 a year, which capitalized at 6 per cent equals \$25,000.

One-third of this would be \$500 a year per million gallons a day. It would take a capital sum of roughly \$8000 at 6 per cent to pay for this pumping, and a supply not requiring any pumping would be worth \$10,000 + 8000 = \$18,000 per million gallons per day.

### Effect on Value by Reason of Not Being Obliged to Filter

If all the water were filtered, and with sufficient storage tanks, it would ordinarily cost about 1.5 cents per 1000 gallons, or \$15 per million gallons a day, or \$4500 a year of 300 days, and for one-third filtered, \$1500 a year. This figure would vary considerably with different water supplies.

The amount \$1500 capitalized at 6 per cent equals \$25,000, and a supply not requiring any filtering or pumping would be worth \$10,000 + 8000 + 25,000 = \$43,000 per million gallons per day.

If the water is used in a plant requiring more than one-third to be pure or more than one-third to be at high pressure, and filtering and pumping are eliminated by the nature of the supply, then the value of the supply would be greater than the above.

The supply which is of the greatest value per unit of amount is one supplying soft and pure water which does not require treatment for softening or filtering, and which is supplied by gravity and does not require to be pumped.

If it is conceivable that all the water must be pure and that all of it must be delivered under pressure, and if the natural conditions will insure these, then the value would be \$10,000 + 25,000 + 75,000 = \$110,000, which is the maximum limit for a supply of one million gallons per day. This limit would not be reached ordinarily. We should say that \$50,000 might be set as the highest value per million gallons a day for ordinary uses.

We have now established tentative limits of \$10,000 for a million gallons a day for a majority of cases, and \$50,000 for exceptional supplies.

It must not be assumed that the foregoing figures are applicable to any particular case, but a method has been indicated by which an estimate can be made for any given general locality of the approximate value of the water for manufacturing purposes.

### Effect of Changes in Conditions

In the earlier days mills were located on streams which would furnish an ample supply of good water for manufacturing purposes. As time has gone on, the supply may have been reduced by takings or may have become inadequate or have become polluted.

If a manufacturing plant has grown so that its water supply has become inadequate or unsuitable, and the plant cannot be moved to a location where the conditions of water supply are favorable, and must be put to unusual expense in obtaining a suitable supply, any excessive capital outlay for obtaining the supply does not add to the value of the property, but in fact may become a burden upon the property and tend to reduce its value.

This additional or unusual expense may have been incurred by the cost of building dams and creating reservoirs; by excessive cost of driven wells; where the water has become polluted, thus requiring excessive cost for purification; or where water must be taken from a city or town supply at high rates.

The base value can be established by a consideration of the cost of the supply to a large majority of establishments which are on a competitive basis with the particular establishment under consideration. A supply with unusual beneficial characteristics will be worth more than the base value. A supply which costs an excessive amount for obtaining and preparing for final use may not add anything to the value of a plant, but may on the other hand cause the total value of the plant to be less than it would be with an economical water supply.

### Example of the Application of the Foregoing Figures

A colored woolen mill, running one shift, will use about 30,000 gal. of fairly good water a day per set of cards when there is a plentiful supply, but satisfactory work can be done with a less amount if necessary.

*a* For the majority of cases where water is taken from a water-power company or from the owner's mill pond, \$10,000 per 1,000,000 gal. a day is a fair base value to assume. $\$10,000 \times 30,000 \div 1,000,000 = \$300$ a set.

*b* Assuming that in a woolen mill one-third of the total amount must ordinarily be pumped, a supply requiring no pumping would be worth $\$18,000 \times 30,000 \div 1,000,000 = \$540$ per set.

*c* Assuming that in a woolen mill one-third of the total amount must ordinarily be pumped and filtered, a supply requiring no pumping or filtering would be worth \$43,000 × 30,000 ÷ 1,000,000 = \$1290 per set.

*d* Based on the more recent agreement mentioned in an earlier paragraph, and using the charge of \$3 per day per million gallons, we should arrive at a value of \$450 per set.

### Water for Condensing

In some plants water is required for condensing as well as for manufacturing, and in some for condensing only. The use for condensing is diminishing in mills, as many of the newer mills are run by purchased electric current and some of the older ones are not replacing the steam plants as they become worn out, but are purchasing current for additional power requirements.

This water does not require treatment for hardness or impurity. When a plant is located at tide water, salt water may be used.

In the manufacturing cities where there are water-power companies, this water is furnished at the same rates as for water power. In mills owning their own water power, the water is usually taken from the mill pond which also supplies water for power.

In some mills the condensing water is used after passing through the condensers for process water, thus reducing the total amount of water required for both purposes and utilizing the waste heat of the power plant.

The value of water for condensing depends upon the adequacy of the supply, the ease with which it can be obtained, the cost of fuel, and the amount of the waste heat from the engine or turbine which can be used for manufacturing purposes. Water for condensing purposes cannot have any value to a plant where the cost of power generated by a condensing plant would be higher than the cost of obtaining the power by some other acceptable method.

Water has no value as power until it is harnessed and is producing power. The potential possibilities for the development of power add value to the riparian rights whenever it becomes economical to develop these possibilities, and also to the land contiguous to the stream.

Water for condensing has no value for that purpose until it is so used, but when it becomes necessary or economical to develop steam power in a certain locality there is added potential value to land so situated that water can easily be obtained for condensing purposes, and such land becomes of more value than other adjacent land where water is not available or is available only at great expense.

Three methods of estimating the increase in value suggest themselves:

1—Its value for condensing can be measured by the net saving produced by its use, taking into account operating and fixed charges. In a manufacturing plant the amount required will depend upon the amount of exhaust steam which can be used in the processes and for heating.

If the majority of plants doing similar work could purchase or obtain water at a moderate cost, other plants in competition with these would be at a disadvantage if it costs them more for condensing water. Before they suffered an actual loss in power production, however, they could pay up to a sum which would represent the saving due to condensing over non-condensing, unless there was a cheaper substitute power available.

The net saving of condensing over non-condensing operation, with engines of 500 hp. and upward, running 10 hours a day with coal at \$6 a long ton, is approximately \$2 a year per hp., of engine load, and for a plant running straight condensing the total yearly saving would be roughly \$2 per hp., with no allowance being made for fixed and operating cost of the plant necessary to get the water to and away from the condensers.

Assuming for the purpose of illustration that it cost \$3 per hp. for the physical structures required to get the water to and from the condensers, and the fixed and operating charges at 50 cents a year per hp., the net saving would be \$1.50 per hp. a year. This capitalized at 10 per cent equals \$15, which represents the capitalized value per horsepower.

Ten per cent capitalization is used here, whereas 6 per cent was used in connection with the value of water for manufacturing purposes. With the increased application of electric current for power there is less use for water for condensing, and the future possibilities for cost of power are subject to a fluctuation of value, whereas good water for manufacturing purposes is becoming scarcer and its use cannot be done away with.

If it takes 60 gal. per hour per hp. for condensing, or 600 gal. per day of 10 hours, the capitalized value of 600 gal. a day would be \$15. This is the maximum value on this basis.

At this rate the value for 1,000,000 gal. a day for a year would be \$15 × 1,000,000 ÷ 600 = \$25,000.

If the exhaust can be used in part or in whole, the value per horsepower would be reduced, but the value per 1,000,000 gal. would remain the same. With varying percentages of exhaust use the value per horsepower would be as follows:

| Per cent of exhaust use | Value per hp. |
|---|---|
| 25 | \$11.25 |
| 50 | 7.50 |
| 75 | 3.75 |
| 100 | 0.00 |

In most colored mills at least as much as 50 per cent, and often as much as 75 per cent, of the exhaust would be used and the value per horsepower would then be \$7.50 and \$3.75, respectively.

For the purpose of illustration, we shall assume that 50 per cent of the exhaust will be used. On this basis the value of water for condensing purposes per set of woolen cards would be 40 hp. × \$7.50 = \$300. If all waste heat of the prime mover can be absorbed in the manufacturing process, the value would be nothing.

If the water can be used for manufacturing purposes after passing through the condenser, a double value cannot be given to it. It would be worth the maximum value of its use for either process purposes or for condensing, and if a portion is used for each purpose the sum of the maximum value for each will represent its value.

Steam turbines under fairly normal conditions require about 120 gal. per kw-hr., or 90 gal. per equivalent hp.

As non-condensing turbines are very uneconomical unless the exhaust steam can be used for manufacturing purposes, it would not be advisable to run non-condensing when there is a scarcity of water. In such a case it would be necessary to install cooling devices for the condensing water or to obtain the power by some other method. The value of condensing water for turbines should not be determined in the manner as indicated above for engines, but might be estimated as indicated below or by comparing the cost of power from condensing turbines with that of purchased current or some other manner which would give reasonable results.

2—Another measure of the value of the opportunity to use the water for condensing is the difference in the cost of equipment and of the operations necessary to deliver the water to the condensers as against some other common way of providing the water as by cooling towers or ponds, taking into account also the relative efficiencies of these methods.

Assume for example that the cost of cooling towers and accompanying apparatus is roughly \$10 a kilowatt.

| | |
|---|---|
| The fixed charges on $10 at 15 per cent a year would be | $1.50 |
| The yearly cost of operation per kilowatt, allowing for lower vacuum, is approximately | 3.25 |
| Cost of make-up water | 0.75 |
| Total cost per year with cooling tower | $5.50 |

Yearly cost with an abundant water supply:

(Cost of intake and piping, pumps, or whatever plant is required, say, $5 per kw.)

| | |
|---|---|
| Fixed charges on $5 at 15 per cent | $0.75 |
| Yearly cost of operation | 1.50 |
| Total | $2.25 |
| Net yearly saving, $5.50 — $2.25 = | $3.25 |

$3.25 capitalized at 10 per cent = $32.50 per kw.
= $24.50 per hp., approx.

Gallons per kilowatt = 120 per hour.

120 gal. × 10 hr. = 1200 gal. a day per kw.

$$\$32.50 \times \frac{1{,}000{,}000}{1200} = \$27{,}000 \text{ per } 1{,}000{,}000 \text{ gal. a day.}$$

Per set of woolen cards requiring about 30 kw.: $32.50 × 30 = $975, say, $1000, when running straight condensing, or $500 when 50 per cent of the steam is extracted and used for manufacturing purposes.

The extra investment in a cooling-tower installation may sometime be offset by the cost of condensing-water intakes, screens, and tunnels, and discharge trenches or canals where water is taken from so-called natural sources. The vacuum obtained when using cooling towers or ponds is rarely ever as good as that obtained where the supply of water is ample.

3—One other method would be by comparison with the charge for such water in communities where it is sold or leased by water-power companies.

Based on charges for water by companies controlling water for manufacturing in manufacturing cities, it would be worth for condensing the same as for manufacturing purposes. We have previously in the paper set up a base of $10,000 per million gallons a day.

600 gal. per hp. a day × 40 hp. = 24,000 gal. a day.

$$\$10{,}000 \times \frac{24{,}000}{1{,}000{,}000} = \$240$$ per set of cards when running full condensing, or $120 when half the exhaust is used.

In most cases this water does not require pumping. By reason of not requiring pumping, the value is increased by $1500, which, capitalized at 10 per cent equals $15,000, making a total of $25,000 per million gallons. This figure would make the value $600 per set of cards for straight condensing and $300 when half the exhaust is used.

### Base Value

In the discussion of the value for manufacturing purposes, we established a base value of $10,000 per million gallons a day. This same figure might be established for water for condensing, at least for manufacturing concerns which are engaged in competition with others located in manufacturing cities where water is sold at the assumed rates.

Compared with the above base figure, an unlimited supply of water would not be of any greater value unless it could be supplied more easily than the water purchased as described above. It would be of less value if the physical structures required to convey it to the condensers cost more and if the water had to be pumped.

### Application to a Woolen Mill

1—Based on the difference in cost of running engines condensing and non-condensing:

| Proportion of steam condensed | Per million gal. a day | Per kw. | Per hp. | Per set of cards |
|---|---|---|---|---|
| All | $25,000 | ... | $15.00 | $600 |
| Half | 25,000 | ... | 7.50 | 300 |

2—Compared with cooling towers and cooling ponds:

| | | | | |
|---|---|---|---|---|
| All | $27,000 | $32.50 | $24.50 | $980 |
| Half | 27,000 | 16.25 | 12.25 | 490 |

3—Compared with sale of water in manufacturing cities:

| | | | | |
|---|---|---|---|---|
| All | $25,000 | ... | $15.00 | $600 |
| Half | 25,000 | ... | 30.00 | 300 |

### Some Tentative Conclusions

1—Base value of water for condensing per million gallons a day ........ $10,000

Under especially good conditions this figure may be as high as ........ $25,000

2—Base value for ordinary colored woolen mills:

| | |
|---|---|
| Value of process water per set of cards | $300 to $450 |
| Additional value of condensing water per set of cards | $300 |
| Lowest value for both purposes, fairly good water | $600 to $750 |

3—As these values may easily vary, a figure might be used in valuation work for all water needed per set of woolen cards in a mill driven by its own power plant, of $700.

4—For special advantageous conditions, the figures would be higher as indicated in the text.

5—The value may be determined by subtracting from its maximum theoretical value the capitalized cost of getting the water to and from the place where it is used and in a proper condition for use.

6—The capitalized cost of obtaining water may be much more than what it would be under ordinary fair conditions, but when it is more and there is no alternative, it puts a burden on the plant and adds nothing to its market value. It may even cause the value to be diminished.

## Discussion

Harrison P. Eddy.[2] The author has presented a very important subject, but one which has not been, I believe, as fully appreciated during the past generation as it is now and as it will be in the future. The author's discussion is so nearly in accord with my own views that I will add only one point which he evidently has intentionally omitted, but which in my judgment is a real factor in establishing the value of water and the value of a plant or plant site. This factor is the difficulty of getting rid of the water after you have used it in the processing. Thirty years ago the disposal of industrial wastes was rarely a serious problem, although the thought comes of the case of Parker versus American Woolen Company, dating back fully 30 years and perhaps more, which is the foundation as I understand it of the decisions which have followed in Massachusetts since that time.

What will be required for the disposal of industrial wastes is exceedingly problematical. It depends upon the population downstream for one thing and very largely on the public sentiment for another. Conditions are complained of today which even five or ten years ago were taken by the public as a matter of course.

There is the further problem connected with the disposal of industrial wastes and that is their effect upon the water used for process purposes farther downstream.

As regards the value of water for dilution purposes there is, first, its use for the disposal of sewage. Ordinarily this is not a very serious problem for industrial establishments, although there is always a small amount. It has been determined, as a very rough rule, that 3 to 5 c.f.s. of water is the quantity required for the satisfactory dilution of the sewage of 1000 persons tribu-

[2] Partner, Metcalf & Eddy, Boston, Mass. Mem. A.S.M.E.

tary to a stream. The estimated cost of sewage treatment today on a relatively complete scale suitable to discharge into a small stream is about $1200 per 1000 persons per year, or capitalized at 6 per cent, about $20,000. The value of diluting water, then, on the basis of 3 c.f.s. per 1000 people is $10,400 per 1,000,000 gal. In other words, if 3 c.f.s. per 1000 population can be drawn and will accomplish the same purpose as the treatment I have suggested, then you can afford to pay $10,400 per 1,000,000 gal., or taking the higher figure of 5 c.f.s., the value drops to $6250 per 1,000,000 gal.

Another example, and that is one that applies to tannery wastes which are worse to treat than textile wastes. At a certain tannery which has a large wool-scouring plant the treatment of industrial wastes amounts to $179 per 1,000,000 gal. If the treatment is eliminated and sufficient diluting water is furnished, then for dilution 50 parts of water would be required for 1 part of industrial waste.

The value of this water for diluting factory waste would be $179 divided by 50 or $3.58 per 1,000,000 gal. daily, equivalent to $1300 per year. Capitalized at 6 per cent the diluting water would be worth about $21,600 per 1,000,000 gal.

The net result of these computations indicates that, for diluting municipal sewage, water has a value somewhere in the neighborhood of $10,000 per 1,000,000 gal., at least for illustrative purposes, and for dilution of industrial wastes the value may be as high as $21,000 to $22,000.

Edwin H. Marble.[3] I would like to ask if either Mr. Main or Mr. Eddy has any figures in regard to the adjustment of the disposal of the water which was claimed to be polluting the stream just below Passaic. Two or three plants were abandoned, and there were figures placed as to what the valuation was and what they should be reimbursed for their plants in that matter. It was a very serious adjustment, they claiming that three plants, two small ones and one large-sized one, were polluting the river, and there was a valuation as to what the river was worth in the first place and the damage caused by polluting it with dyestuffs, etc., and I have heard that the fish were all killed.

If my memory serves me right, the plants made the claim that their plants had an additional worth because they had a water supply, and the City of Passaic offset that claim by the damage done to the water by the waste or by the dye-house waste, and there was a valuation set on the water power and the privileges, and also they tried to set up a counter-claim. The case was tried before three engineers. This is an engineering problem that I have never heard thoroughly discussed.

William Heffernan.[4] I am right in that community where the Passaic River is polluted. It seems the pollution of the river dates back some years, and the Standard Bleachery, where I am located, contributed to the damage done to the river. At our particular plant we installed about three years ago, although I was not there at the time, a sewage system for taking care of the waste before it goes into the river. A large trunk sewer was started about ten or twelve years ago, I have been told, and it extends from Newark up to Paterson. It is about 4 ft. in diameter at Paterson at present, and when it reaches Passaic it is about 12 ft. in diameter, and continues on until it connects with the disposal plant of the Passaic Valley Sewage Commission at Newark.

In connection with the mills there has been great agitation going on in this district for some time, and the mills are doing all they can in cooperating with the Passaic Valley Sewage Commission in order to clean up the river. At the Standard Bleachery Company, where we have a system for treating our waste, only 10 per cent of the wastes can go into the trunk sewer; the other 90 per cent must be treated by us and returned to the river in good condition. The Passaic River up to a few years ago had been an open sewer for the sanitary wastes and the mill wastes. Now the sewer is taking care of the sanitary wastes, and the mills are supposed to treat 90 per cent of their industrial wastes.

Passaic is on one side of the river and Carlton Hill, where the Standard Bleachery is located, is on the opposite side of the river, and I have noticed that the fish are now swimming up the Passaic River. Within the next few years probably all the industries down there will be taken care of and the river will be as nearly normal as before. In fact, motor boats are quite popular, where before they could not use the river. A white boat would turn black in a few weeks; and a white house a mile away would turn black from the fumes from the river. In my opinion it means that all large plants must install distillation systems of their own.

The Standard Bleachery Company was not compensated by the State or Government, in whole or in part, for the installation of its sewage disposal system.

Marcus K. Bryan.[5] There are two methods apparently used in this paper for the determination of value, one being used for condensing water and the other for industrial or process water. These are fundamentally different. The method used for condensing water is to capitalize the earnings accruing from the use of the condensing water, and the method used for the process water is to capitalize the average cost of water to several plants similarly situated. The method used for condensing water seems beyond criticism. There is a distinction between condensing water and process water which seems important to me, that being the fact that process water is indispensable and generally without a substitute, whereas condensing water is not essential in the operation of the plant. Thinking along that line, I wondered if the values established in the paper were not perhaps the minimum values. If the water supply is damaged, and the plant is reimbursed for the damages, that amount would, if capitalized, take account of the injury done to the earning power of the plant by the destruction or injury to the water supply. If a building or some other physical property or element of property were destroyed, it could be replaced, and perhaps its value would then be its replacement cost.

It is not likely that the destruction of a building would affect the earning power of the plant as destruction or elimination of the process water would, and the thought from that in my mind was that the difference between the values of water established in damages and the value established by the capitalized cost of obtaining it in the locality where the plant was located might be too large.

There appears to me another element of value in process water which has not been taken into account. Physical structures like buildings and machinery are replaced from time to time and depreciate in value, and generally are replaced with better buildings and machinery due to advances in the art. Supplies of process water, perhaps, are being depleted or the demand for them is increasing as industry increases, and may it not be that the value of process water appreciates through the years, and therefore might there be an element of value which admittedly is difficult to determine but is not in the values as determined?

### Author's Closure

I have not seen any report on the settlement of the claims and

[3] Pres., Curtis & Marble Mach. Co., Worcester, Mass. Mem. A.S.M.E.

[4] Standard Bleachery Co., Carlton Hill, N. J.

[5] Chas. T. Main, Inc., Boston, Mass. Mem. A.S.M.E.

counter-claims for damages to industrial plants on the Passaic River.

In order to keep the paper as simple as possible, I purposely omitted any discussion of the problem of getting rid of the water after it had been used for manufacturing purposes.

I am glad that Mr. Bryan has said something as this question has been under discussion among my associates for a number of years. Many thoughts relating to the subject have not been incorporated in the paper. The object was to see if we could get some reasonable method of determining the figures which we put into our valuations of industrial properties for the item of water for manufacturing purposes. If anybody can send in any discussion in writing which will be of assistance we shall be glad to have it.

# Comparative Performance of Looms With Plain and Roller Bearings

By GEORGE H. PERKINS,[1] BOSTON, MASS.

THE tests reported in this paper were undertaken to obtain authentic comparative data on the effect of the application of roller bearings on loom performance, with special reference to the following factors:

1 Production gain
2 Maintenance cost
3 Power saving.

With this purpose, complete performance records were obtained from two groups of looms, each consisting of thirty-two 81-in. Hopedale "Nordray" automatics, in regular operation at the plant of the Naumkeag Steam Cotton Co., Salem, Mass.

These loom groups were identical in all respects, except for bearing equipment, and were under test and close observation for 26 full weeks of normal mill operation.

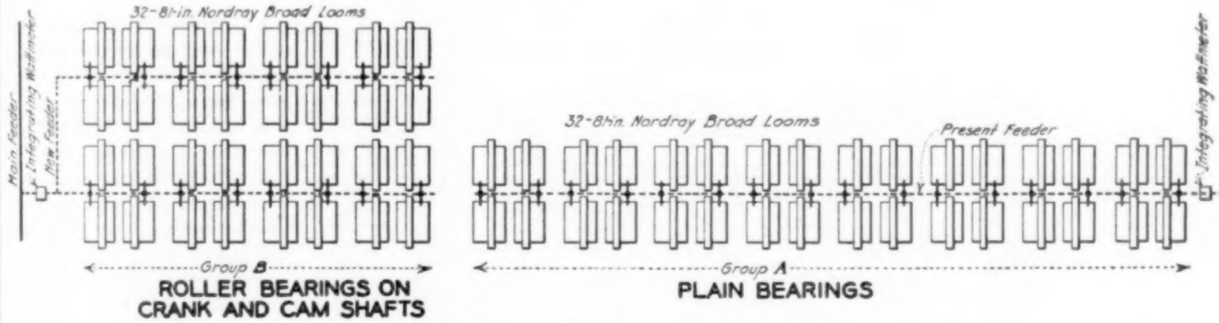

FIG. 1 LOOM ARRANGEMENT AT NAUMKEAG STEAM COTTON CO., SALEM, MASS.

Reliability of results was insured, not only by the long duration of the test and number of looms observed, but also by the elimination of such variable factors as age and condition of looms, type of drive, specification of cloth woven, atmospheric conditions, and character of attendance and supervision.

### General Data

| | |
|---|---|
| Plant | Naumkeag Steam Cotton Co., Salem, Mass. |
| Test started | March 14, 1927 |
| Test finished | Sept. 24, 1927 |
| Duration of test | 26 weeks. (Mill stopped for annual shutdown from July 2 to July 18 and also on holidays, April 19, May 30, and Sept. 5.) |
| Loom equipment | 81-in. Hopedale Manufacturing Co. Nordray automatic broad-sheeting looms |
| Age of looms | In use for 2 years, 6 months to Mar., 1927, including about 6 months of day and night operation |
| Motor equipment | $^{3}/_{4}$-hp. Design A, KT-121, General Electric Co. loom motors with waste-packed bearings, 1800 r.p.m., 220-volt, 3-phase, 60-cycle. Pinions: 15 teeth, 8 pitch, and $1^{1}/_{2}$-in. face |
| Pick-counter equipment | Veeder pick counters were used from Mar. 14 to July 2. All counters were changed during annual shutdown period. Root pick counters were used from July 18 to Sept. 24 |
| Normal loom speed | 115 picks per minute. Speed checked at frequent intervals |
| Cloth data | 81-in. Pequot brown sheeting, 68 ends, 72 picks, and 1.43 yd. per lb. |
| Watt-hour meters | Westinghouse Type OA watt-hour meter in feeder for each loom group. Meters were furnished and calibrated by Salem Electric Lighting Co., Salem, Mass. The meters were also recalibrated in test location on July 27, 1927 |
| Loom arrangement | The loom groups were arranged as shown on accompanying floor plan, Fig. 1. This plan also indicates location of watt-hour meters |

### Test Methods and Observations

The general methods followed and principal observations taken during the test are outlined as follows:

1 *Production.* Pick-counter readings were taken on each loom daily after closing time.

All counter readings were recorded on a weekly record sheet and the total picks per loom per day and per week were computed and cross-checked at the end of each week's run.

2 *Maintenance.* All loom stoppages covering periods of 5

| | Average | 970 | 855 | 11.37 | 988 | 823 | 12.00 | 1.71 | 3.60 |

[1] Weeks including holiday.
[2] Loss.

minutes or over were carefully recorded by observer, including time of stop and start and the cause for the interruption of operation.

In case of all stoppages due to breakage, replacement, or repair the loom part involved, with name, pattern number, and cost, was recorded, together with the actual time lost.

All time required for changing warps was also recorded in the same manner.

A complete typical maintenance record for one loom No. 3450 of Group A is given in Table 1, and similar data were obtained for each of the test looms.

3 *Power.* Readings of the watt-hour meters on both groups were taken twice daily and records made on the weekly record sheet with the production.

Hourly readings were also taken on each Monday, beginning at 7:15 a.m. to determine the effect of the week-end shutdown on the starting power consumption.

4 *Observers.* Throughout the entire test an experienced observer, entirely familiar with loom operation and construction, was in constant attendance and recorded all of the test data.

5 *Weekly Records.* The complete results for each week for production and power were tabulated and computed on each original record sheet, which was duplicated, thus eliminating any errors resulting from transfer of data. Similar sheets were prepared for each of the 26 weeks of test.

6 *Attendance.* The test looms were operate d by the weavers and fixers regularly assigned to them, in the ratio of 12 looms per weaver and 50 looms per fixer.

## Test Data

The principal data of the test are shown in the accompanying tabulations as follows:

*Production and Power.* Table 2 gives the complete weekly and total results for production and power as follows:

*a* Weekly production for each group in (1000) picks (columns 3 and 6)

*b* Total production for each group in (1000) picks, with weekly average for test (columns 3 and 6)

*c* Percentage production gain for Group B over Group A for each week and average percentage for entire test (column 9)

*d* Weekly power consumption for each group in kw-hr. (columns 4 and 7)

*e* Total power consumption for each group for entire test in kw-hr., with weekly average for test (columns 4 and 7)

*f* Percentage power saving for Group B over Group A for

each week and average percentage for entire test (column 10)

*g* Ratio of production to power (1000 picks per kw-hr.) for each week and each group, with average ratio for entire test (columns 5 and 8).

In Table 3 the production power ratios are separately tabulated, and the percentage gain of these ratios for Group B over Group A is given by weeks and as an average for the entire test. All data in Table 3 are also shown graphically in Fig. 2.

*Maintenance Cost.* The complete summarized record of all replacements for every loom of both groups is given in Table 4. This table includes the name of part, pattern number, unit cost,

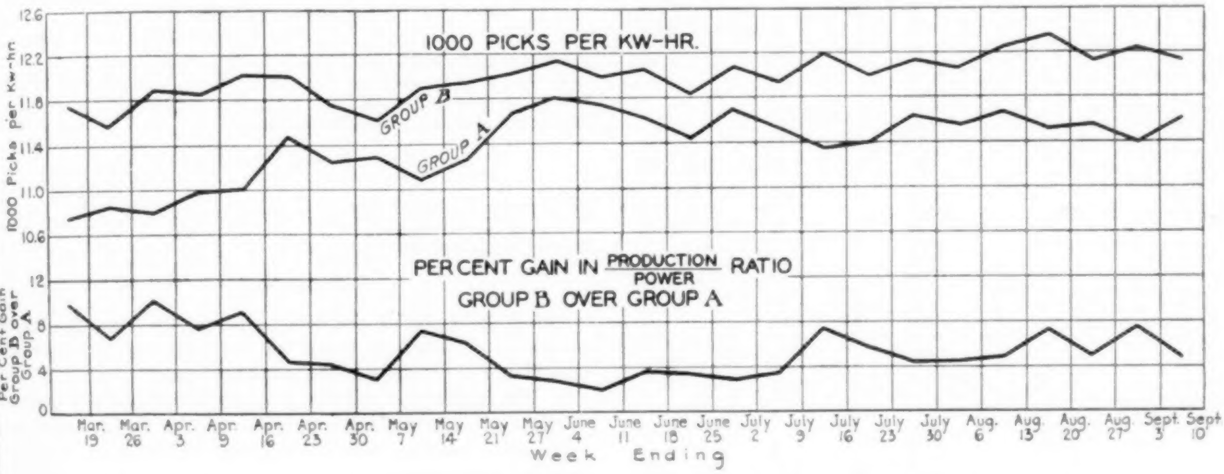

FIG. 2 COMPARISON OF PRODUCTION-POWER RATIOS OF LOOM TESTS AT NAUMKEAG STEAM COTTON CO.

actual number used, and total cost for all replacements made during the entire test.

### ANALYSIS OF RESULTS

Analyses of the test results in detail are presented as follows:

PRODUCTION

| | Group A, plain bearings | Group B, roller bearings |
|---|---|---|
| Total production (1000 picks) | 252,487 | 256,822 |
| Average (1000) picks per loom per week | 303.5 | 308.7 |
| Production: | | |
| Total, in yards | 97,410 | 99,082 |
| Yards per group per week | 3,746 | 3,811 |
| Yards per loom per week | 117 | 119 |
| Additional yards per loom per week | .... | 2 |
| No. of warps used during test | 156 | 167 |

The production gain for Group B shown above results from easier and smoother loom operation, with consequent less stoppage for repairs, replacements, and normal loom operations by the weavers.

The following tabulation presents a segregation of the total test time in loom-hours and in percentages of total.

TIME ANALYSIS

| | Loom-Hours | | | |
|---|---|---|---|---|
| | Group A | Per cent | Group B | Per cent |
| Total productive time | 36,592 | 92.02 | 37,220 | 93.59 |
| Total stoppage for changing warps | 303 | 0.76 | 302 | 0.75 |
| Total stoppage for replacements and repairs | 260 | 0.66 | 113 | 0.28 |
| Total stoppage for normal loom operation | 2,610 | 6.56 | 2,130 | 5.38 |
| Total test time | 39,765 | 100.00 | 39,765 | 100.00 |
| Total stoppage time | 3,173 | 7.98 | 2,545 | 6.41 |
| Average loom efficiency, per cent | | 92.02 | | 93.59 |

*Maintenance.* Study of the maintenance records (Table 4) shows a large proportion of the replacements for both groups to be parts of the pick motion and related members such as check straps, lug straps, pick cam points, pickers, picker sticks and bolts, rocker shoes and bolts, and shuttles. These parts are subjected to repeated shocks and always comprise the major part of loom upkeep.

These parts for both groups are segregated in the following comparative table:

NUMBER OF PARTS REPLACED

| | Group A, plain bearings | | Group B, roller bearings | |
|---|---|---|---|---|
| | No. | Cost | No. | Cost |
| Check straps | 31 | $1.86 | 13 | $0.78 |
| Lug straps | 8 | 0.84 | 4 | 0.42 |
| Pick cam points | 18 | 9.90 | 8 | 4.40 |
| Pickers | 51 | 4.59 | 14 | 1.26 |
| Picker sticks | 39 | 2.14 | 23 | 1.26 |
| Picker-stick bolts | 34 | 1.02 | 14 | 0.42 |
| Rocker shoes | 5 | 2.25 | 2 | 0.90 |
| Rocker-shoe bolts | 14 | 0.42 | .. | .... |
| Shuttles | 21 | 30.24 | 8 | 11.52 |
| Total cost | | $53.26 | | $20.96 |

The marked reduction in the number of these parts for Group B must be attributed to the shock-absorbing characteristics of the roller bearings used.

*Power.* The following table gives a summary of the power data obtained for the entire test.

| | Group A, plain bearings | Group B, roller bearings |
|---|---|---|
| Total power for test, kw-hr | 22,210 | 21,410 |
| Average kw-hr. per week | 855 | 823 |
| Max. kw-hr. per week | 930 | 880 |
| Min. kw-hr. per week including holiday | 700 | 670 |
| Total loom hours | 39,765 | 39,765 |
| Kw. per loom per hr. | 0.56 | 0.54 |
| Hp. per loom per hr. | 0.751 | 0.723 |
| Rated hp. of motors | 0.75 | 0.75 |
| No. of motor fuses replaced | 21 | 5 |

Study of the weekly power consumption in Table 2 shows a marked consistency throughout, and that practically all variations

in power are directly reflected in changes in the production obtained for same period.

The ratios of production to power in thousands of picks per kilowatt-hour as shown in Table 3 are particularly consistent throughout the entire test.

## Summary of Results

The principal results of the test are summarized as follows:

### Production Gain

| | Group A | Group B |
|---|---|---|
| Total production for test, yards | 97,410 | 99,082 |
| Production gain for test, yards | ... | 1,672 |
| Production gain over Group A, per cent | ... | 1.71 |
| Production gain per loom per week, yards | ... | 2 |
| Production gain per loom per year (50 weeks), yards | ... | 100 |

### Maintenance Cost

| | Group A | Group B |
|---|---|---|
| Total cost of replacements for test | $131.00 | $65.62 |
| Cost per loom per week | 0.1574 | 0.0789 |
| Saving per loom per week | ....... | 0.0785 |
| Saving per loom per year (50 weeks) | ....... | 3.93 |

### Power Saving

| | Group A | Group B |
|---|---|---|
| Total power for test, kw-hr | 22,210 | 21,410 |
| Power saving, kw-hr | ... | 800 |
| Power saving, per cent | ... | 3.6 |

## Conclusions

Before summarizing the conclusions drawn from these tests, particular attention is called to the following factors which have important bearing on the results obtained:

1 The application of roller bearings to the looms of Group B was limited to four bearings only per loom out of a possible ten.

No roller bearings were used on the friction shafts or rocker shafts of either group.

This limited application of roller bearings unquestionably restricted to some extent the advantages to be gained from their use.

2 In comparing the loom efficiency of both groups, special note should be made of the high existing efficiency of the looms of Group A. This fact makes any production gain shown the more creditable.

3 The existing loom conditions of Group A were excellent, and particular attention was given to general upkeep and systematic lubrication. These favorable conditions have an important bearing on the possible power savings.

The following factors all contribute largely to the authenticity of the results under the conditions as outlined:

1 Duration of test
2 Number of looms operated
3 Elimination of variable factors and uniformity of conditions
4 Close observation of all looms for all stoppages for any cause.

In view of the above factors and the marked consistency of all observations throughout the test, the following conclusions may be drawn:

1 The production gain of 1.71 per cent obtained for Group B results directly from the use of the roller bearings, through effecting easier- and smoother-running looms and thus reducing the stoppage time for repairs, replacements, and the normal operations incident to weaving. The commercial value of the increased production varies so widely in different plants that no attempt will be made by the author to present definite cost data in this paper.

2 The material reduction of maintenance cost must be directly attributable to the application of roller bearings, through the partial elimination of the shocks incident to loom operation, particularly in connection with the pick motion.

3 The net power saving shown (3.6 per cent), while not large, is creditable in view of the limited bearing application and generally excellent condition of the looms with plain bearings. Power saving must always be considered secondary to the gain in production and the reduction of maintenance costs. The value of this power saving will vary in different localities with the cost of power, and this gain will therefore not be evaluated in this paper.

It should be noted that these tests were made in a modern textile mill of the highest type and one widely known for its efficiency. Larger production gains and increased savings in power and maintenance costs could undoubtedly be shown in the textile mill of average efficiency.

# Progress in the Woodworking Industries

## Contributed by the Wood Industries Division

Executive Committee: Wm. Braid White, *Chairman,* Paul H. Bilhuber, *Secretary,* James S. Mathewson, Sern Madsen, and Thos. D. Perry

DURING the past year the wood industries of the United States have shown, by and large, a growing interest in the fundamental question of the quantity and quality of the remaining supplies of domestic timber. In part this interest has been due to the work of the National Committee on Wood Utilization, which was set up three years ago by Secretary Hoover of the Department of Commerce, and which is composed of representatives of the lumber, woodworking, forestry, and engineering interests. The A.S.M.E., in the person of the present chairman of the Wood Industries Division, is represented on this committee, which is working to educate the wood industries in eliminating waste, in the need for an understanding of scientific methods of timber conservation, and in preparing the way for the ultimate adoption of standards in machinery and in machine methods. The work of this committee is by no means the only work of the kind being done, but it must be mentioned as a contributing factor to the year's progress.

Not enough has become known among the industries, metal and non-metal alike, concerning the very fine work which has been going on for a number of years at Madison, Wisconsin, where the Forest Products Laboratory of the Forestry Service of the United States carries on its increasingly valuable researches into every aspect of the growth and use of wood. The practice of throwing open to technical men from the woodworking industries free courses at the Laboratory in the gluing of wood, in the science and art of plywood building, in crating and boxing, and especially in the seasoning and drying of lumber, has been continued, and it may confidently be affirmed that all who have had personal contact with these admirable courses of instruction feel more than repaid for the time spent in them. If the woodworking industries were more alive to the work which the Forest Products Laboratory is doing, they would be insistent in pressing Congress to be more generous in appropriating the needed funds.

### Timber Conservation

Timber conservation is no longer a matter merely of academic interest. At the annual convention of the National Lumber Manufacturers' Association, held this summer in Chicago, the tone of the discussions was extremely serious, indicating clearly that the lumber men, who have been the chief scorners of all talk about diminishing supplies, are themselves already thoroughly alarmed at the situation. This fact lends point to the position taken by the Wood Industries Division of the A.S.M.E., which two seasons ago undertook to investigate the situation as to possible supplies of commercially and industrially usable timbers from tropical countries, such as the Philippines, British India, and Central and South America. In the Progress Report of one year ago it was possible to say something briefly about this research, and now, a year later, it can be stated that some quite definite steps have been taken. A comprehensive bibliography of books, papers, and articles in several languages, upon every aspect of the tropical-woods question, has been prepared by Major George P. Ahern and Miss Helen Newton of the Tropical Plant Research Foundation of Washington, D. C. In addition to this extremely valuable pioneer work, which is paving the way for the scientific investigation of a subject as important as it is little understood, the Wood Industries Division has given special attention to presenting aspects of the question at various meetings of the Society. Thus, at the first national wood industries meeting of the A.S.M.E., held last November in Chicago, after the 1926 Progress Report had been written, the whole question of timber supply was taken up by Major Ahern, whose paper produced valuable discussions and debates, in which experts from the Forest Products Laboratory, tropical foresters, and representatives of large wood-using industries took part. At the second national wood industries meeting of the Society, held in Grand Rapids during the month of October last, the same subject was taken up again, and has come to general attention.

### Research

Last year's report made mention of a project to secure a research into the properties of machine saws and cutting blades, investigating the laws governing the behavior of these tools in use, and leading to the formulation of recommendations to manufacturers and users whereby closer agreement may be arrived at in regard to saw cuts, sharpening, standardization of cutting edges, etc. Considerable difficulty was experienced in obtaining a working committee, but the task has now been accomplished and the first general meeting will have been held before this report has been published.

The research in spark-arrester design and use is proceeding through the help and cooperation of the Pacific Coast Local Sections of the A.S.M.E.

### Progress in Developing Woodworking Machinery Along Engineering Lines

Last year some mention was made of the subject of woodworking education, with special reference to the attitude assumed by directors of technical schools and colleges. It is not possible at this time, unhappily, to say anything more encouraging than was said a year ago. Woodworking remains, in the minds of engineering educators, the cut-and-fit art it was a generation or two since; nor is there much probability of fruitful change save through the direct intervention of the woodworking industries, and their insistence upon a proper appreciation of the fact that woodworking has now perforce been driven into the engineering ranks.

Meanwhile it is possible to say something more or less definite about the progress which has been made during the year in developing woodworking machinery along engineering lines.

In the first place, there can be no doubt as to the trend of design of woodworking machinery. It is toward inbuilt electric motors, rendering each machine self-contained. In the same way one may note a trend toward the adoption of multiple-operation machines, while frequency changers are being more and more used to give machines the advantage of both high- and low-speed operation. This practice is becoming more and more common in connection with shaping, grinding, jointing, and (some types of) planing machines.

Another new departure is to be found in the gradual invasion of the field by tools driven by compressed air, and some newly designed shapers and routers so driven are being successfully

exploited. The primary cost of compressed-air operation is greater than where electric current is used, but the maintenance cost is sufficiently lower to offset this in most cases.

The use of high-speed steel for cutter heads and milled knives is also developing, and in shapers, matching, and molding machines cutting tools made of this material are rapidly replacing the older carbon-steel types.

It is worth noting that the speed and accuracy of woodworking machinery are often underrated by engineers who are not closely in touch with modern mill developments. The fact that wood is a material relatively easily worked sometimes is allowed to obscure the equally important fact that woodworking machinery is keeping all the time a little ahead of its material and is constantly being adapted to closer, more accurate, and more rapid operation. Even if the factor of rapidity be left out of the picture, it is certain that all these developments make in their way for conservation of a timber supply already dangerously depleted.

Turning again for a moment to this question of the supply of the raw material of woodworking—the timber itself—it is interesting to note that in addition to the movements mentioned at the beginning of this Report, others have been initiated by the lumber interests. Among these may be mentioned:

1 Completion and adoption of the American Lumber Standards for softwood, thereby unifying sizes, grades, and shipping practice in respect of by far the greater part of all such lumber annually produced in this country;

2 Steady development of hardwood grading standards;

3 National waste-prevention contests, bringing out new machinery, methods, and suggestions for preventing waste, using materials now being wasted, and improving the quality of the product from the log; and

4 Adoption of a research program covering the properties and uses of wood.

### Wood Finishes

In the domain of wood finishing, it is worth noting that the use of nitrocellulose solutions (known as "lacquers") in the place of varnishes has been steadily increasing during the past year. More than half of all the furniture exhibited at the winter and summer furniture shows this year was lacquer-finished. The difficult technical problems of applying these new finishes to woods are gradually being worked out, and woodworkers are coming to regard lacquer as not merely interesting and novel, but as definitely valuable and advantageous when rightly prepared, applied, and managed. It is distinctly pleasing at this point to discover that one result of the growing interest in these lacquer finishes is to be found in definitely improved work in the sanding of wooden parts as they come from the mill, in preparation for the application of the lacquer. Clean and smooth sanding is necessary when lacquers are used, and of course there are numerous other subsidiary advantages to the finished product, flowing from this improved practice.

The research into the possible use of tropical hardwoods, reported here as part of the work of the Wood Industries Division of the A.S.M.E., is being backed up practically by certain woodworking industries, which report trials, and in some cases adoption, of tropical hardwoods in place of domestic varieties, but the subject is still in too indefinite a shape for more positive comment.

Plywood continues to find favor where strength and resisting power are factors, and the art of fashioning it continues to become more exact, thus tending to the utilization of woods which otherwise in many cases have been wasted.

The evolution of the wood industries into engineering arts proceeds steadily, and the place of the woodworking technicians among the members of the A.S.M.E. becomes yearly more thoroughly justified.

# Increasing the Production of Woodworking Machines by Use of Direct-Connected Alternating-Current Motors

By W. A. FURST,[1] DETROIT, MICH.

THE electrical industry has continuously kept pace with the progress of woodworking machine-tool development. This mutual and coordinated progress has attained results almost undreamed of a few years ago. The aim of both the builder of machine tools and the builder of electrical equipment has been to coordinate their efforts with the greatest economy and the highest utility, and, with but few exceptions, the individual electric drive of machine tools has met the demands of the most progressive and exacting ultimate users.

For an example, let us take an individual machine, such as a molder or planer and matcher. If this machine were belt-driven there would probably be a countershaft connected with a main lineshafting, or a single motor coupled to the countershaft, and also the necessary belt running from the countershaft to the machine and the necessary belts on the machine which would take care of the cutter heads and the feed of the machine. Old-timers are familiar with the maintenance required for the belts, pulleys, bearings, etc. of an installation of this character. We all know that with the belt drive there is a limit to the operating speed as determined by the permissible linear speed of the belt in feet per minute. We know also that to obtain the best results on a finished surface it is desirable to have the greatest number of knife marks per inch length of material. To obtain the most desirable number of cuts with a belt-driven machine it is necessary to assume a maximum belt speed of possibly 5000 to 6000 ft. per min., and also to use a cutter head having a large number of knives. Any operator who has had the task of setting up and grinding knives on a cutter head appreciates what is required to set and grind a knife head of this character.

An advantage which may be gained by using direct-connected motor drive—that is, a built-in individual motor on each cutter head, and in addition a motor on the feed—is the possibility of using a cutter head with fewer knives and of running the motor at a higher speed than attainable by the use of a belt drive. Further, with the use of individual motor drive it is possible to operate any one head individually, allowing the other head to remain idle. Another decided advantage is that if the work becomes jammed in the machine the cutter head will automatically stop, because of the overload protection on the motor, which latter may be arranged so that jamming or other trouble on any one cutter head will immediately stop all cutter heads and the feed mechanism at the same time. This is impossible in the case of a belt-driven machine unless the belt slips off or breaks. As to the class of work accomplished, if the belt is loose enough to slip it means that the tool or cutter head will slow up when it is passing over a hard spot in the material, whereas the electric motor will have a tendency to maintain practically a constant speed at all times and give the same finish over the whole length of the material.

Up to the present time the standard alternating-current motor with a full-load speed of approximately 3500 r.p.m., operating on a 60-cycle circuit has been applied to the cutter heads on the above-mentioned machine. To increase the production of the plant it is quite possible and feasible to take the standard motors which were normally designed for 60-cycle service and increase the frequency and voltage of the main circuit in direct proportion so that higher speeds may be obtained on the cutter heads. Under this condition, assuming that the feed remains the same, we should obtain a greater number of knife marks per inch length of material, and thereby obtain a smoother surface. However, by increasing the speed of the cutter head and the feed at the same time we are able to increase the production of the machine in a direct ratio with the speed of the cutter head and in accord with the class of work desired. By this is meant that if a high grade of finish is desired the cutter heads should be increased in speed but the feed should remain the same. However, if the same results are desired as are being obtained under present conditions the feed should be increased in the same proportions as the speed of the cutter head.

The following information will be of interest to those desiring to increase the production of their machines, using motors direct-connected to the cutter heads.

The feed motor may be designed for four-speed operation with approximately a 3 to 1 ratio, that is, having a high speed of approximately 1800 r.p.m. in four steps, giving respectively 1800, 1200, 900, and 600 r.p.m.

When we speak of the ordinary standard alternating-current motor we at once think of a motor operating on a 60-, 50-, or 25-cycle circuit. By "cycle" in alternating current we mean that the current builds up from zero to its maximum, and returns to zero again and then does so in the opposite direction for the succeeding half cycle. There are two alternations for each cycle. By the number of cycles—that is, 60, 50 or 25—we mean the number of complete cycles per second. In other words, in a 60-cycle circuit there are 7200 alternations per minute. To obtain the various speeds, the motors are built with different numbers of poles. In practice these run in multiples of 2, from 2 to the upper limit of 18. For the smaller-sized motors it is not desirable to have a large number of poles as it makes the cost prohibitive because of the considerably greater amount of labor and material required in winding.

As the speed of an alternating-current motor is determined by the number of poles of the motor and the frequency of the supply circuit, this can be expressed by the following formula:

$$\text{R.p.m.} = \frac{f \times 60 \times 2}{N} = \frac{f \times 120}{N}$$

where $f$ is the frequency of the line and $N$ the number of poles.

The high-speed motors are of the same simple construction as standard squirrel-cage motors. They consist (Fig. 1) of two main parts, namely, the stator or stationary part and the rotor or rotating part. The speed of these motors ranges from 3600 to 18,000 r.p.m.

Up to the present time 18,000 r.p.m. has apparently been the highest speed required in commercial practice; however, it is quite feasible to obtain higher speeds, and motor manufacturers

[1] Manager Engineering Division, Westinghouse Electric & Manufacturing Company.

Contributed by the Wood Industries Division and presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, February 24, 1928.

are prepared to quote on such motors as special applications. By referring to Fig. 2, the speeds for 2-, 4-, 6-, and 8-pole motors at various frequencies can be readily noted. For example, a 2-pole motor operating on a 120-cycle line will run at 7200 r.p.m., or operating at 200 cycles the same motor will have a speed of 12,000 r.p.m.

The speeds as given on this chart are the synchronous or no-

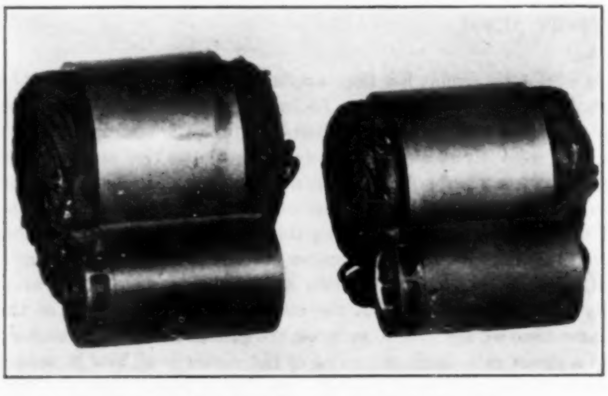

FIG. 1 STANDARD SQUIRREL-CAGE MOTORS

load speeds. The drop in speed of an induction motor from no load to full load, or the slip, is proportional to the amount of resistance in the rotor or rotating circuit. As the starting torque of the motor is directly dependent upon the amount of slip of the rotor, it can be seen that for various applications the slip of the motor should be different, and therefore the full-load speed will necessarily be lower with the higher slip. In most cases it is very easy to figure the full-load speed from the curve, knowing the slip. In the standard motor the slip is usually from 2 to 5 per cent, but where the starting conditions are severe, small motors may have a slip as high as 10 per cent. This probably would be an exceptional case, and the motor would

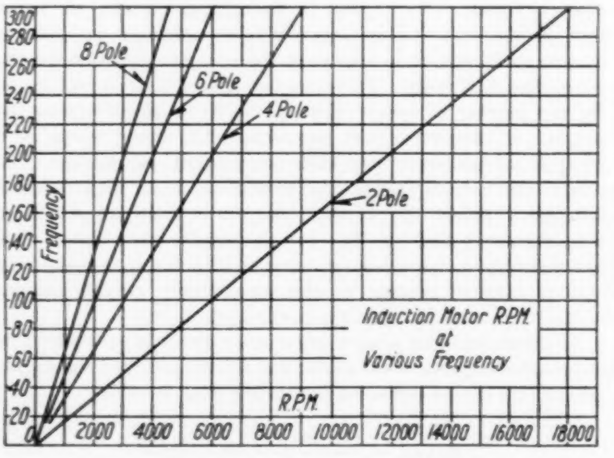

FIG. 2 INDUCTION-MOTOR SPEEDS AT VARIOUS FREQUENCIES

only have this high percentage of slip when the starting torque was very high. Assume, for example, that a motor has a slip of 5 per cent and a synchronous speed of 7200 r.p.m. The full-load speed would then be 7200 r.p.m. minus 5 per cent of 7200 r.p.m. or 6840 r.p.m.

In this class of high-speed motors the ratings are all based on a continuous duty, with a temperature rise of 40 deg. cent., and the motors are designed to operate at various frequencies, depending upon what speed is desired up to certain limitations for the particular size employed. For the larger sizes, such as those used on molders or planers and matchers, 6000 r.p.m. at 100 cycles apparently is the maximum speed at which it would be desirable to run the cutter head. For the smaller-sized motors, where a smaller cutter head is used, such as on spindle shapers and carving machines, higher motor speeds may be obtained in proportion. By referring to Fig. 3, at the right-hand columns B and C, it will be noted that the voltage varies at the different frequencies given in column A. In the case of a 110-volt motor operating at 120 cycles, it would require 165 volts at 180 cycles, and when operating at 60 cycles, 55 volts. If the motor is designed for 220 volts and 60 cycles, the values in column C should be multipled by four. However, if the motor is designed for 440 volts at 60 cycles, column C should be multiplied by eight. It can readily be appreciated that at 100 cycles this would give approximately 756 volts at the motor. Under this condition of operation it would be desirable to change the motors over from 440-volt connection to 220 volts at 60 cycles and then have them operate at approximately 396 volts at 100 cycles. However, if it were desired to operate the 440-volt motors at 60 cycles to a speed of approximately 4800 r.p.m. or 80 cycles, the voltage then would rise only to approximately 584 volts.

For any conditions which arise on this subject wherein the motors in use are to be operated at higher frequencies, the subject should be referred to the manufacturers of the electrical

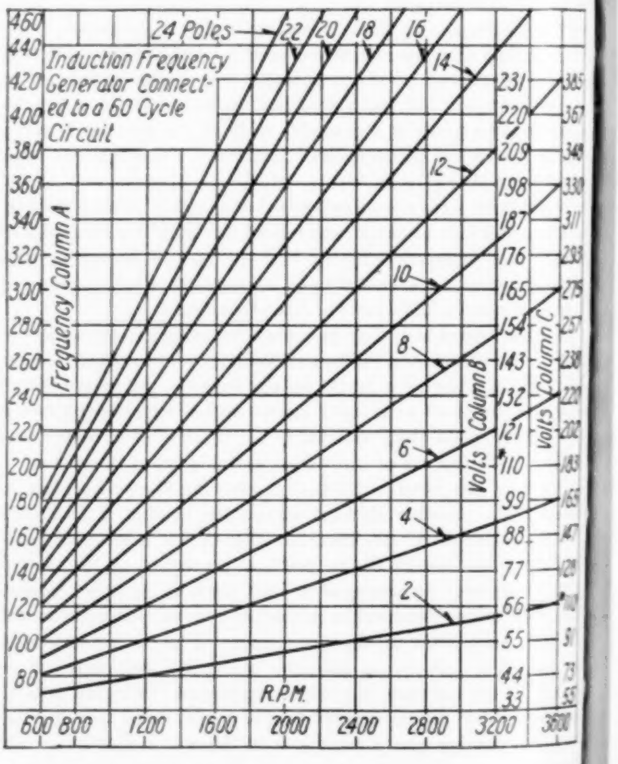

FIG. 3 FREQUENCY-SPEED-VOLTAGE RELATIONS OF AN INDUCTION FREQUENCY GENERATOR CONNECTED TO A 60-CYCLE CIRCUIT

equipment for their comments and recommendations. As stated above, in some cases the present motors may be operated at the higher frequencies and voltages without any change whatsoever in the connections of the motors.

By referring to columns B and C of the chart, at 300 cycles the motor designed to operate at 110 volts and 200 cycles would operate at 168 volts and 300 cycles, while the motor designed for 110

volts and 120 cycles would have to operate at 275 volts and 300 cycles, and if it had been designed for 220 volts and 120 cycles, it would operate at twice 275 volts, or 550 volts. Because of the necessary insulation required for this voltage and the restricted space available on these comparatively small motors, it is desirable to keep the voltage as low as possible. This requirement is to a certain extent governed by local conditions in the operating plant, and it is highly desirable in all cases to get the recommendations of the motor manufacturer for the various voltages to be used.

Probably the majority of the motors employed in the woodworking industry have 2, 4, 6, or 8 poles. The synchronous speed of an alternating-current motor is obtained by dividing the number of alternations per minute by the number of poles. For example, consider a 2-pole motor operating on a 60-cycle circuit; 60 cycles is equivalent to 7200 alternations per minute, which, divided by 2, gives a motor speed of 3600 r.p.m. Since a motor may not have less than two poles, 3600 r.p.m. is therefore the maximum speed which can be obtained on a 60-cycle source of supply. Therefore in order to obtain higher speeds it is necessary to increase the frequency, or the number of cycles per second.

There are several methods of obtaining high frequency for operating high-speed motors. Probably the simplest one is by utilizing the induction frequency changer. This consists essentially of a standard wound-rotor type of alternating-current motor with certain modifications in the design so that it will give the proper voltage at any predetermined frequency. It can only be used where alternating current is available, irrespective of the frequency of the incoming line. The fundamental theory of this generator is such that it has virtually the same characteristics as an ordinary transformer.

If we take a standard alternating-current wound-rotor type of motor, pass a 60-cycle current through the stator and hold the rotating element in the stationary position, we can obtain 60 cycles from the rotor. By making certain changes in the winding of the rotating element we can also obtain any desired voltage. Under normal conditions, when the motor is operating at synchronous or no-load speed, there is practically no frequency

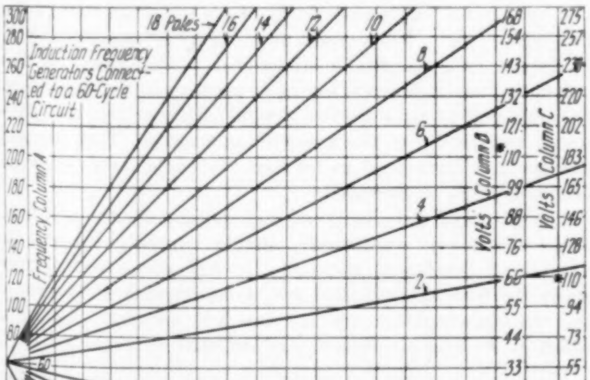

FIG. 4 CHART SHOWING SPEED AT WHICH A GIVEN ROTOR TYPE OF INDUCTION MOTOR MUST BE DRIVEN IN ORDER TO OBTAIN A GIVEN FREQUENCY

generated in the rotor circuit. Therefore, if the rotor is revolved in the opposite direction from which it would revolve as a motor, there will be generated in the rotating element a frequency above 60 cycles, and a certain voltage, depending upon the speed.

Fig. 4 shows at what speed a given rotor type of induction motor, revolving in the opposite direction, will have to be driven in order to obtain any given frequency. As an example, assume that it is desirable to obtain 120 cycles from a 60-cycle circuit. By referring to column A and following the 120-cycle line to the right until it intersects the 4-pole-motor curve, and then dropping down the vertical line which intersects the frequency line at right angles, we find that this motor would have to be driven at 1800 r.p.m. in the opposite direction. Therefore, by using a 4-pole generator direct-connected to a 4-pole, 60-cycle, squirrel-cage motor, a complete motor-generator set for obtaining 120 cycles is obtained.

Again, let us assume that it is desirable to obtain 120 cycles.

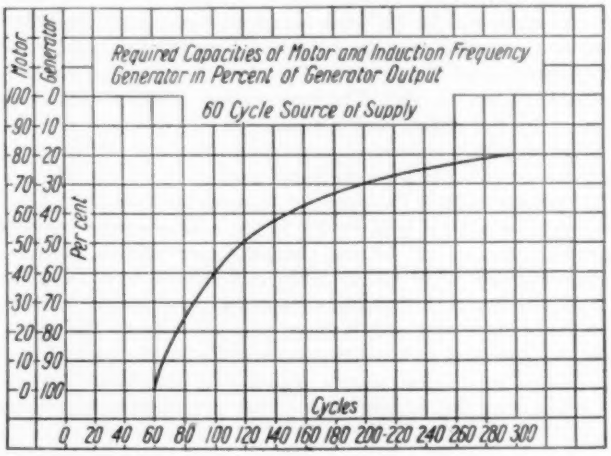

FIG. 5 REQUIRED CAPACITIES OF MOTOR AND INDUCTION FREQUENCY GENERATOR IN PERCENTAGE OF GENERATOR OUTPUT. 60-CYCLE SOURCE OF SUPPLY

It is understood that 1800 r.p.m. is the most desirable speed for driving a squirrel-cage motor operating from a 60-cycle source of supply. Following the 180-cycle line in column A until it intersects the 8-pole curve, and then down the vertical speed line, we find that this machine can also be driven at 1800 r.p.m. The same induction frequency generator could be wound to give 180 cycles at either 99 volts or 165 volts, depending upon the class of service desired. In general, in order to obtain a higher number of cycles the induction frequency generator will require a correspondingly higher number of poles if it is desired to direct-connect it to one of the standard squirrel-cage motors. Hence it may be observed from the curve that a 16-pole, 60-cycle generator would be required to obtain 300 cycles by using the standard 1800-r.p.m., 60-cycle motor.

Fig. 5 shows the comparative sizes of both generator and motor for any kilowatt output. The required capacity of the motor and the induction frequency generator are given in percentages of generator output. For example, assume that it is desired to generate 100 kw. at 120 cycles. Following the 120-cycle line until it intersects the curve, and then on the horizontal line to the left of the intersection, it will be noted that the generator capacity will be 50 per cent and that of the motor, 50 per cent. Consequently in this case the generator will take 50 kw. from the 60-cycle line, the combined sum of the two always equaling the total kilowatt output. Again, assume that it is desired to have a 100-kw. output but at 2000 cycles. Following the 200-cycle line until it intersects the curve and then on the horizontal line to the left, it will be observed that the generator will take 30 kw. from the line and the motor 70 kw.

For any given size of generator the power input is the same irrespective of the kilowatt output at the various frequencies. The kilowatt output from the generator is directly proportional to the increase in speed, and it is necessary for the motor to supply the additional power required to drive the generator at the increased speed. In other words, assume that we have a motor-generator set of 10-kw. output at 120 cycles. As stated above, the power input of this generator from the 60-cycle source of supply will be 50 per cent of the output, or 5 kw. The motor will supply the additional 5 kw. of the output as mechanical power at the generator shaft.

Supposing it is desirable to generate 180 cycles, this same generator will still take 5 kw. from the source of supply, but the kilowatt output will be increased in direct proportion to the speed required to obtain the 180 cycles, or by referring to the curve, it will be found that the excitation of the generator at this point of the curve will be $33^1/_3$ per cent, the motor supplying $66^2/_3$ per cent. In this case the excitation from the line is 5 kw. or $33^1/_3$ per cent of the output. Therefore the output of the machine is 15 kw. It should be remembered, however, that these figures are theoretical, and in practice it will be found that the output will vary somewhat, depending upon the efficiencies of the driving motor and the generator itself.

If by any chance the operator happens to have only direct current available, it is necessary to use a direct-current motor-generator set, and in this case the generator would be of the alternating type. The motor-generator set would have the same characteristics as the induction-frequency-generator set; that is, the generator output will increase proportionally to the speed, but it is necessary to increase the size of the motor to supply the additional mechanical energy required at the higher speeds.

In the event that it is desired to obtain two different frequencies with the alternating current available, it is necessary to use a two-speed alternating-current motor. As an example, assume that 180 cycles and 120 cycles are desired. From Fig. 3 we note that by using a standard 1800-r.p.m. 60-cycle motor, an 8-pole generator will be required to generate 180 cycles. The same curve shows that the 8-pole generator will have to be driven at 900 r.p.m. in order to generate 120 cycles. By referring to Fig. 2, it will be found that with a 60-cycle source of supply, a 4-pole and 8-pole motor would be necessary to obtain 1800 and 900 r.p.m. This pole combination can be taken care of on a single squirrel-cage motor. Such motors can be designed for combinations of 2 and 4 poles, 4 and 8 poles, and 6 and 12 poles, to give the two different speeds required.

In some cases the standard 60-cycle control may be used on the higher frequencies without any change whatsoever. However, the electrical manufacturer should be told of this change to ascertain whether the various parts may be used for the higher frequencies. The same general principles of control will apply to the motors operating on the higher frequencies as those used on 60-cycle service.

It can readily be appreciated that with a combination of the induction frequency generator and the various pole combinations on the motor, a range of speed for any particular type of machine may be obtained.

## Discussion

C. FAIR.[2] Engineers who have kept in close touch with electrical developments for industrial purposes will agree with the author that the electrical industry has "kept pace with the progress of woodworking machine-tool development." It is, however, not so evident that either the woodworking-machinery manufacturer or the woodworking industry as a whole has shown any very marked tendency, until recently, toward taking advantage of these developments. In the last few years competition has become so keen in the wood industry that it has brought about many new developments in woodworking machinery as well as changes in existing tools.

The design of many of the newer machines depends largely upon the direct-connected or built-in motor obtainable for practically any speed required.

It is interesting to note the influence of the electric motor in machine development. At first the motor was used merely as a means of breaking up that type of long-distance lineshaft drive where the shafts were driven from one to another, from building to building, and from floor to floor. From the very beginning it was found that the breaking-up of long lineshaft transmissions resulted in a saving of power sometimes as much as 60 to 80 per cent. Because of the great saving in power due to breaking up long mechanical transmissions the saving of power was looked upon as the principal advantage of the electric drive.

Short shafts driven by motors or group drives were advantageous because they allowed a better grouping or arrangement of tools, irrespective of the location of the main lineshaft.

Individual drives at first were found advantageous principally for large tools remotely located. As the demand grew for larger tools the individual motor drive became a necessity partly because of the advantages of the adjustable-speed motors, partly because of the necessity of placing them where they could be better served by cranes, and partly because of the power required to drive them.

For some time, however, the saving in power cost has been looked upon as a small part of the saving in productive cost, since the power cost for the majority of industrial plants falls within $1^1/_2$ to 3 per cent. The saving of 50 per cent of power cost would mean an actual saving of $^3/_4$ to $1^1/_2$ per cent of the productive cost. Labor costs are roughly 50 per cent of the productive cost, therefore a saving of only 15 per cent in labor cost would mean an actual saving of approximately $7^1/_2$ per cent. It is therefore obvious that rapid-producing machines and labor-saving devices are of the greatest importance. The frequency changer and high-speed motor form one of the means by which production can be increased.

The electrical manufacturers, and the manufacturers of high-speed machinery particularly, should carefully consider the merits and benefits of standards for frequencies and voltages above the 60-cycle range and not, as has been done by some of the machine builders, try to establish arbitrary standards which in the long run cannot help but react unfavorably.

# The Pulp and Paper Industry and the Northwest

By C. C. Hockley,[1] Portland, Ore.

*The purpose of this paper is not to disclose the details of any one process, but rather to furnish a glimpse of the industry as a whole, and in particular that part of the industry using wood fiber, and consequently standing timber, with its relation to the Northwest, its present extent of production and consumption, and its hopes for the future.*

*A picture of the continental, and in fact the world production and consumption, is given, together with a glimpse of our population and rate of growth. There is also a short description of the different processes used. In the latter part of the paper a few of the points in a mill where waste occurs are enumerated, and means for avoiding at least part of these wastes are suggested.*

Our first paper mill was built at Philadelphia in 1690, and made paper from rags. As late as the year 1810, while we had 200 mills, they made but 3000 tons of paper per year, of which 500 tons was newsprint.

Canada built her first mill in 1880, but the industry did not develop largely there until after 1900.

In fact, wood pulp has been largely developed as a paper source since the days of the Civil War, and in 1869 we find that while the country had 677 mills they used only 2000 cords of wood during the entire year. So we see that our use and development of wood pulp has been during the last 60 years. Progress has been phenomenal, and it is a matter of public knowledge that wood pulp in some form is now used for the production of newsprint, wrapping paper, glassine paper, explosives, roofing,

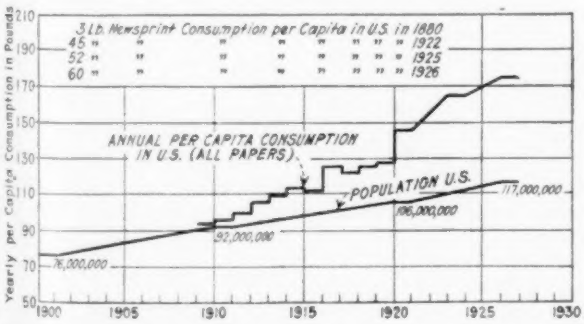

Fig. 1 Yearly Consumption of Papers per Capita in the United States

clothing, imitation silks (Rayon), wall board, car wheels, paints, etc.

A study of the consumption of papers of different kinds in different sections of the country reveals some interesting conditions, such as the fact that newsprint is consumed in quantities varying with the literacy of the population. Also, general paper consumption will vary with the volume of industry and its resulting use of wrappings and advertising.

These facts give the West Coast a high cons mption per capita, due to the high percentage of English-speaking people and high educational standards.

[1] Consulting Engineer.

Contributed by Oregon Section and presented at the Seattle Meeting, Seattle, Wash., August 29 to 31, 1927, of The American Society of Mechanical Engineers.

## Population

In 1930 we may estimate the population of our continent as 140,000,000. This has been a growth in the United States from 38,000,000 in 1870, when our wood-pulp era may be said to have started, to 75,000,000 in 1900, when Canada began to contribute pulp, and to 115,000,000 in 1925, when Newfoundland began its larger developments.

Alaska has reached the day of its development, as has British

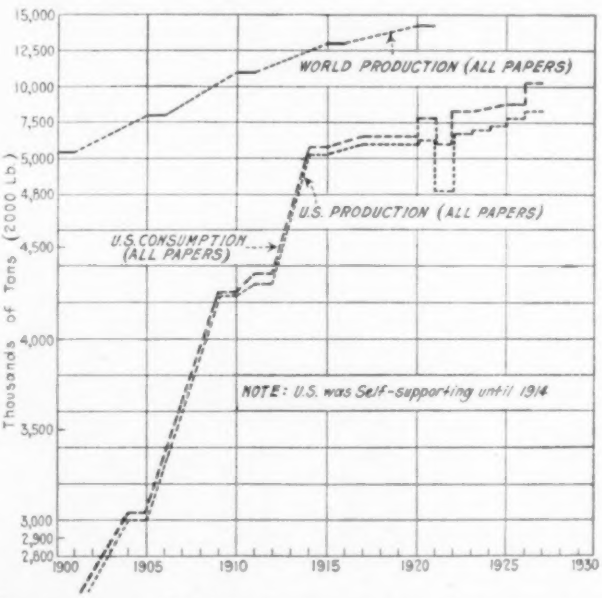

Fig. 2 Curves Showing Production and Consumption of Papers in the United States

Columbia and our Western States, and this last frontier will by 1930 be contributing paper to our continental population of 140,000,000. To complete the picture of our populations, and therefore our users of paper, we must remember that the world looks to us for its future supply, and while we will have about 140,000,000 population on this continent the world population will be about 1,750,000,000, and we find that our continent with 8 per cent of the world's population is and will be using over 50 per cent of its production. (See Figs. 1, 2, and 3.)

While estimates are but guides, at best, it seems logical to assume that the other 92 per cent of the world's population, outside of North America, will later on demand more paper of all kinds than we can supply.

## Consumption

The people of the United States are the world's best customers at present, and in 1926 our consumption of over 10 million tons of paper products gave us the staggering consumption of 175 pounds per capita, while of newsprint alone we used 3,500,000 tons in 1926, or about 60 pounds per capita.

But these high consumptions of paper are not general throughout the world as we may see by the following figures, and while we, as users of all kinds of paper, consume about 175 pounds per year per capita in the United States, Great Britain uses only

about 80 pounds, Germany 45, and Russia 5 pounds per capita.

Fig. 1 shows our increase in annual per capita consumption of all kinds of paper from 75 pounds in 1900 to 175 pounds in 1926. An increase in newsprint consumption from 3 pounds per capita in 1880 to 60 pounds in 1926 indicates a growing consumption per capita, and we would surely be conservative if we assumed the present rate of consumption for future estimates.

### Production

But what has taken place in the way of production during these mad years of climbing consumption?

The United States staggered along until about 1913 with a newsprint production equaling her consumption and then, with our first realization of wasted forests and scarcity of raw material in the East, Canada came to the rescue and we find that, while the United States' production of newsprint has increased from 1,300,000 tons in 1913 to only 1,600,000 tons in 1926, Canada's production has increased from 300,000 tons in 1913 to almost

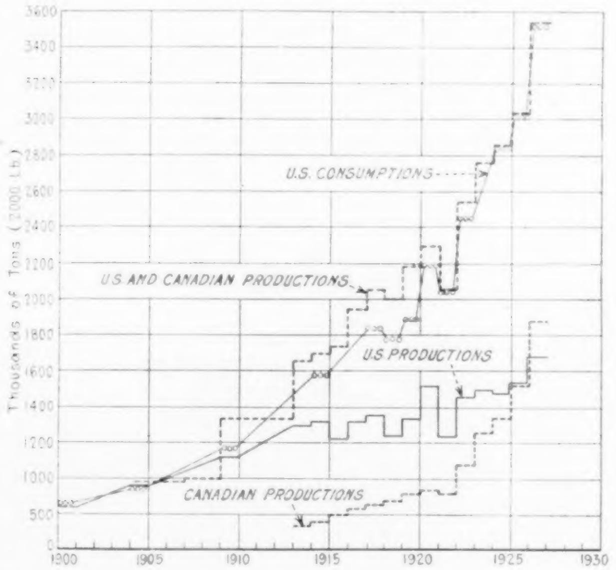

Fig. 3 Curves Showing Newsprint Production in the United States

1,900,000 tons in 1926, and the entire production of both countries has practically all been consumed on this continent. (See Figs. 1, 2, and 3.)

Our continental productions of newsprint for February, 1927, as reported by Trade Associations, confirms the figures given above and were as follows:

| | |
|---|---|
| Canada | 150,773 tons |
| U. S. A. | 121,318 tons |
| Newfoundland | 14,250 tons |
| Mexico | 1,250 tons |
| Total | 287,591 tons |

A study of the charts, which show population, per capita consumption, and production may answer some of the questions as to over-production, and we find that our difficulty in the future is going to be to keep up to consumption, without sacrificing our forests, and our final hopes are reforestation and fire protection—subjects too big to more than mention here.

### Trade Area

Fig. 4 shows an estimated population, in the Western States, for the year 1930 (based upon the increase in population from 1900 to 1920), while the shaded area shows the territory which is competitive or advantageous and reached by either rail or water from pulp and paper mills in the Northwest.

To the population of 17,000,000 in 1930 in the twelve States which are the legitimate trade territory of the Northwest, one must add an estimated population of British Columbia and Alaska of 1,000,000, making a total of 18,000,000, and Secretary Hoover in a San Francisco address predicted that the year 1950 would find a population of 30,000,000 west of the Rockies.

The East Coast is reached by a water freight rate which makes it competitive territory, and the Orient offers the Northwest the untouched and undeveloped hordes comprising half of the world's population—all looking to us for future supply.

Fig. 4 Population and Trade Areas as Estimated for 1930—Shaded Area Indicates Territory Which Is Competitive or Advantageous

This population in our Western trade territory (18,000,000) gives us an estimated consumption of 1,500,000 tons of all kinds of paper in 1930, as against a consumption of 1,200,000 tons in 1926.

There are 41 mills in Washington and Oregon making an annual production of 1,000,000 tons of pulp and 800,000 tons of paper and board.

This means that by 1930, without going either to the East Coast or to the Orient, we will be able to sell on the West Coast an additional 700,000 tons of paper per year, or 2335 tons per day.

In addition, we have still open, as legitimate markets for our products, the Southern and Eastern ports, on at least a competitive basis, and the Orient with favorable freights from the Northwest.

### Pulp Wood

The following figures taken from Government sources are essential to an understanding of our raw-material supply:

It is estimated that our original stand of merchantable timber was about 5250 billion board feet in the United States, of which 2750 billion remains (1250 billion west of the Rocky Mountains).

In addition to the above merchantable timber figures it is estimated that on the continent we have about 1750 billion board feet of timber (without using any of the waste from the merchantable timber) suitable for pulp. This would give us about 2500 million cords, but as much is inaccessible, and as it is an estimate only, we should not use a figure of over 2000 million cords, and a very conservative estimate reduces this amount to as low as 1000 million cords. As the United States used in 1926 about 10 million cords, we have an apparent wood supply for 100 years at our present rate of consumption, and without considering increased population, increased per capita consumption, or any new use or export business.

We should not, however, feel that wastes can continue, and should learn a lesson from our experience in the Eastern part of

the United States where the one time "boundless forests" have almost disappeared.

A sound reforestation plan is our only safe program.

The hysterical statements which indicate a boundless supply of wood, as well as an attitude which would not allow full production to the limit of our ability to consume, should be avoided.

Just a word as to our pulp wood supply in the Northwest, and still leaving out the wastes from merchantable stands:

| | |
|---|---|
| British Columbia has about | 42 million cords |
| Alaska, which may be considered as all pulp wood, about | 100 million cords |
| United States, west of Rockies, about | 500 million cords |
| Total | 642 million cords |

This supply can take care of our entire continental consumption on our present basis for 60 years, and would be a perpetual supply, if reforested.

### Economics

In a study of the economics of our situation we need not be frightened by talk of freight rates, cost of wood, costs of power, sales costs, etc., because it is after all not a question of the cost of any one item which will decide the result as to profit and loss but is the sum total of costs of the product delivered to the consumer, and in this respect the Northwest stands in a position second to none.

This completes our survey of available wood, possible markets and our Northwest's possible share in the industry's development, and the facts stated indicate that we have the opportunity to meet a world need in production; that we need not fear overproduction; and that we are in an economically sound position, but with each individual mill having its own problems to solve.

### Processes

As in the preceding paragraphs of this paper, the discussion will be limited to those processes using wood as their raw material, and such valuable pulp sources as straw, rags, bagasse, cane, etc., will not receive treatment.

With small variations we find that practically all of the wood pulp is made by one of the four following processes:

1 Ground wood or mechanical process
2 Sulphite process
3 Soda process
4 Sulphate process

Fibers, as made by any one of the above processes, may be combined and formed into a sheet of paper, the quality of which will depend upon either the species of wood used, or the degree of refinement used in its manufacture.

*Mechanical Pulp* is so called because it is produced by holding the log or block under pressure against a revolving grindstone. The stone tears the fibers from the block and the result is "ground wood." Fig. 5 illustrates one type of grinder used for this work. Mixed with water, the fibers are screened and refined and form the basis of newsprint paper (75 to 85 per cent) and also the bulk of boards and papers requiring no particular strength or fineness of texture.

*Sulphite Process.* This process is a combination of mechanical and chemical treatment of wood, the block or log being reduced to as nearly a uniform chip as possible, these chips then being treated or cooked in a closed digester under steam pressure.

The solvents, with which the chips are "cooked" are a bisulphite of lime and sulphurous acid, and, following the cooking, the dissolved matter as well as the solvents are washed out, leaving the fiber only.

No recovery of the chemicals is made by this process, except that of the gases which are relieved during the cooking process.

The same screening and refining of the pulp is used in this process as in making mechanical pulp.

*Soda Process.* This process differs from the sulphite process principally in its use of an alkali (soda) as a solvent and in the recovery of its chemicals by a system of evaporating, burning, and leaching.

*Sulphate or Kraft Process.* Like the soda process, this is a combination process. Chips and a solvent of sodium sulphate (salt cake) are employed, and this process also has an elaborate recovery system for reclaiming its chemicals.

Any one of the processes, or their modifications, will make a fiber, and the choice of process will depend upon the species of wood available, power available, kind of paper or pulp desired, etc.

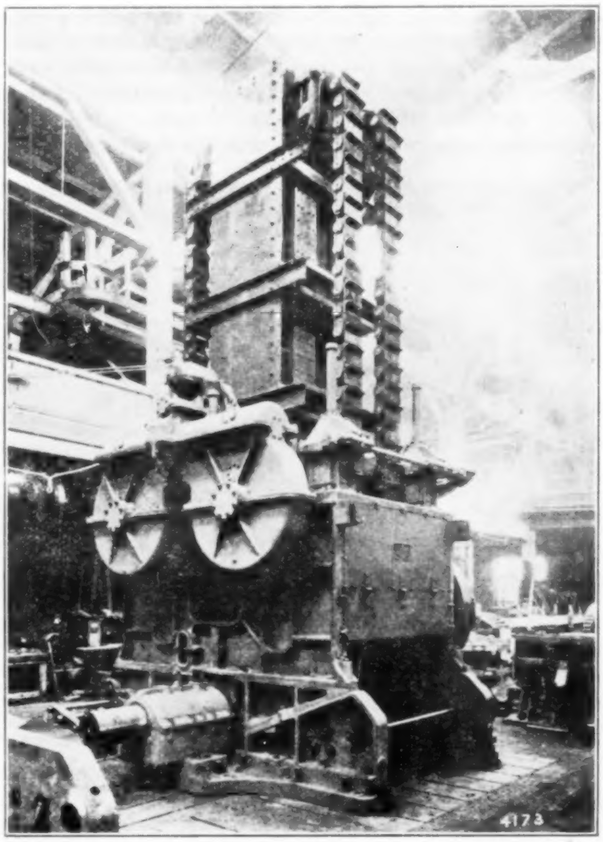

Fig. 5 Magazine Grinder Used in the Production of Mechanical Pulp

From the standpoint of yield per cord, the mechanical process produces more wood pulp, as it merely uses the entire block, shredded, while any chemical process, although giving a longer and stronger fiber, loses all of the dissolved material and produces only about one half as much wood pulp per cord.

### Wastes and How to Avoid or Remedy Some of Them

The discussion of wastes in a manufacturing industry often leaves out of consideration the losses or wastes which result in failure of the concern. Before taking up the losses of fiber in the pulp and paper industry the author would mention the losses due to management, incorrect design, and equipment. A proper cost system would doubtless reveal most of the following, which for lack of a better name may be termed general losses:

*General Losses.* Low production often occurs as a result of bad design, poor construction, unbalanced equipment, or breakdowns, and generally a large proportion of the manufacturing costs continue regardless of magnitude of production. As an example, a sulphite-pulp mill with a capacity of 40 tons per day produces but 30 tons. Its cost per ton at the mill is, say, 36 dollars, of which the raw material will amount to 16 dollars, leaving a balance of 20 dollars per ton, which in the case of 40-ton production would decrease to 15 dollars. In other words, 5 dollars per ton has been wasted in administration, taxes, depreciation, labor, etc.

*Labor.* During periods of low production, labor is wasted. In well-run newsprint mills the labor required will run down as low as about one man per day ton, but in many cases two or more men per day ton are required. This is an economic waste, since surely our prosperity depends upon the largest production, of good quality, possible per man.

Turnover costs are difficult to ascertain, and whether replacement costs 25 or 500 dollars per man will never definitely be known, although it cannot be doubted that it is an expense and results in decreased production.

FIG. 6 TUMBLING BARRELS, OR BARKING DRUMS

The outstanding reasons for the use of fewer men are:

(*a*) Improved design of mills, with consequent proper routing of processes and materials. A good example is the use now of pulp, in the paper mills, in what is known as "slop" form. This means the saving of pulp machinery, as well as men formerly engaged in forming the screened pulp into "laps," storing and handling the laps, and then again reducing the laps to "slop" form at the paper mill. As the screened stock contains but one-half to one per cent fiber, the water must be removed in order to form the "laps." This is done by a partially submerged wire-screen cylinder revolving in a vat of the screened pulp. The water escapes through the screen (taking with it some of the finer fibers), and leaves a coating of fibers on the cylinder. This fiber is removed, pressed, and folded into "laps."

(*b*) Advancement in the design and capacities of machinery has reduced man power per ton, as is shown in the following cases: "Barking drums" (Fig. 6) replacing knife barkers have in many cases reduced the men required in the wood-preparing rc m by 50 per cent. Magazine grinders of large capacity also have reduced the number of men required, as they require no more attention than the smaller types.

The modern paper machine, with its width of as much as 284 in., as compared with the 120-in. width of 15 years ago, and its speed of as much as 1500 ft. per min., as compared with 300 ft. per min. 15 years ago, has boosted the output from 25 tons of paper per day to from 125 to 150 tons per day—all with the same labor.

*Design.* Aside from the question as to whether or not the mill location is an economic one, the number and size of units used, the layout and arrangement of the different departments, the synchronization of the different processes, and the handling of material, all will contribute to the success or failure of the project, and correct design will assist in eliminating the wastes of both construction and operation. Time for study before building, a step too often hurried, is as important as any one step in the development of this industry.

*Power.* Power losses assume a conspicuous place in the survey of wastes, due to the fact that they are so large a proportion of total costs of manufacture (15 to 25 per cent), but often they are not realized, and in many cases are hard to locate or compute. An example of this difficulty is the existing cases of a pulp-and-paper mill which generates its own steam power in two different boiler houses; generates electrical energy in one of the boiler houses; generates energy by means of water wheels direct connected to machinery, and purchases electrical energy from a local public utility. To complicate the problem, the purchased as well as the generated electrical energy is used in both plants, and on occasions the power generated acts as a stand-by service for the utility company. The correct distribution and the correct charge for power are almost impossible of solution, and the engineer in the larger boiler house may perhaps be forgiven for reporting an efficiency of 108 per cent when it is discovered that he uses as fuel both coal and wood-room refuse, neither of which is weighed or analyzed as used.

The day has arrived for public utilities, and is fast approaching for pulp and paper mills, when efficiency will be the order in the power department and the wastes will be the criterion by which the success of the company may be gaged.

The losses due to incorrect design or construction of furnaces are not only reflected in the repair bill but result in either the wastes of an excessive flue gas temperature or a high carbon content of the ash.

Money expended for soot blowers is not a waste if they save fuel or avoid shutdowns, nor is the outlay for superheaters or better boilers if they result in higher efficiencies, lower repair bills, and possibly the generation of sufficient power with the cost of both steam and electrical energy reduced. High pressures and superheat permit high-pressure turbines to exhaust into low-pressure mains and digesters. A higher cost per steam-generating unit results, but there is a saving in the number of units, amount of labor, repairs, power costs, etc.

Failure to provide for a system returning all condensate to the boiler house results in the use of more makeup water, more fuel and more labor, which is truly a waste. Proper insulation of steam lines and digester, although much discussed, rarely is completely achieved. The cost of lubricants does not represent the only waste due to the use of poorly designed drives, poor bearings, etc.; again more labor, shutdowns, and more power result. The purchase of bearings by price and size results in waste.

The practice of driving many machines from one line shaft results in waste, as there is usually continuous operation of part of the equipment, and a loss of power, excess consumption of lubricant, extra labor, etc., accompany the maintenance of the line-shaft equipment.

*Fiber Wastes.* Since wood-pulp costs and consequent paper costs are made up largely (15 to 50 per cent) of the cost of wood, considerable time and study should be given to avoiding its waste. For the purpose of this paper, the problem will be taken up at the wood-preparation department, and will not consider the statements, perhaps hysterical, of wastes in logging operation.

One cannot expect to use black knots or rot in pulp; therefore, there will always be an apparent loss from this source, because all such defects must be cut out, and the operation always carries with it the discard of a certain amount of the good fiber. This waste, however, may be reduced to a minimum through care on the part of the knife barkers, and by using barking drums where possible. It is now history that the tumbling barrel or barking drum reduces the waste from about 20 per cent to 6 per cent. This figure applies to small wood as found in Eastern Canada, and will not be accurate for larger woods. The waste material from the above operation is burned, but the heat value is barely sufficient in most cases to consume the refuse, due to moisture in the bark, and certainly the good wood sacrificed is a total waste. This waste has resulted in the development of bark presses which squeeze out the water and leave the bark with a possible fuel value above that needed to evaporate the water contained. The correct solution of this problem is to reduce the 20 per cent to about 6 per cent, and burn or waste only the bark and such knots or rot as have no fiber.

Logs received at the mill weigh, or at least the railroads charge for a weight of, 7500 lb. per thousand board ft. log scale.

It is generally considered that one board foot log scale weighs about 7500 lb. and this is finally resolved into the following figures:

| | |
|---|---|
| Lumber | 3700 lb. |
| Sawdust | 2300 lb. |
| Refuse: | |
| (a) Bark | 750 lb. |
| (b) Waste Wood | 750 lb. |
| Total | 7500 lb. |

This may be assumed to give, where large Western woods are used, a weight of 6000 lb. as prepared for the pulp mills; an amount equal to about 1.6 cords, not considering the waste wood or bark.

This figure also compares with the average weight of 3800 lb. of a prepared cord of wood in Eastern Canada or Eastern United States. But it is found that one cord of prepared wood (3800 lb.) per ton (2000 lb.) of ground wood is required, and roughly two cords of prepared wood per ton of chemical fiber. It cannot all be waste, but what has become of the 1800 lb. of prepared wood which disappears in making a ton of mechanical pulp, and the 5600 lb. which disappeared in making a ton of chemical pulp? The following may be considered:

(a) Moisture will make up perhaps 30 per cent of the total weight of wood having a dry weight of 2660 lb. per prepared cord. Also, there is a loss in making a ton of ground wood of 660 lb., or 33 per cent, all of which is either lost in slivers, sawdust, or in the fibers lost in the white water.

(b) Of the two cords used in making a ton of sulphite there would remain, after deducting 30 per cent moisture, a weight of 5320 lb. of dry wood, and from this is finally secured 2000 lb. dry weight of chemical pulp.

Chemical analysis, however, shows that only about 50 per cent of the weight of most species of wood is cellulose so 50 per cent may safely be eliminated except for the recovery of by-products.

Deducting matter other than cellulose there remains 2660 lb., and from this is produced but 2000 lb. of chemical pulp or cellulose. Again there is a loss of 33 per cent during the process of manufacture. The operations causing a part of this loss will be mentioned.

*Wood-Preparation Losses.* In making the chips, unless the knives be kept sharp, slivers are made which are either thrown out or, if cooked in the digester with the uniform chips, are not reduced to fiber and pass to waste as screenings. Slivers may account for as much as 2 per cent of the prepared wood. Sawdust made in the preparation of the chips will amount to about 3 per cent of the weight of the prepared wood, and much more will be wasted if the knives and crushers are not kept in condition. This is all waste, except for possible fuel value. It is notoriously true that slivers are hard to refine, and the tendency is to burn them or dump them in the stream and hope that they will disappear.

*Grinding Losses.* In the mechanical-pulp process the nature of the grinding and the variation in the character of the wood makes it impossible to avoid the production of slivers. The quantity may, however, be reduced by attention to the surfacing of the grinder stones, careful regulation of the pressure, and care in keeping the pockets of the grinders filled.

The character of the wood also affects the amount of slivers

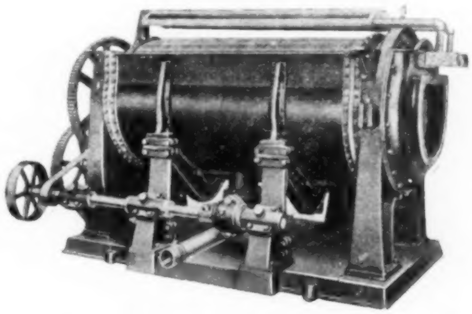

Fig. 7 Type of Filtration Apparatus Designed to Eliminate Waste

from a chemical cook, although care in the preparation and uniformity of the chips have much to do with the result.

*Pulp Washing Losses.* After the pulp has left the digesters, in the case of chemical pulp, and before screening, it must be washed and all chemicals removed. At this point large wastes occur as the pulp is drained through perforated plates while being washed with a large amount of fresh water. If the perforations through which the wash water drains be large, or the pulp be forced through by the action of hose or other washing systems, the loss is very great and the escaping fiber is either discharged into the river (sulphite process), or is burned during the recovery of the chemicals (sulphate process).

Waste sulphite liquor will amount to about 2000 gallons per ton of pulp. Attempts to reclaim fiber in the wash liquor from the sulphite process have been made, and by-products such as alcohol, glue or size, tannin and turpentine have been secured. The waste liquors have also been neutralized and the water partially evaporated (Robson process) and the residue used for road binder, or if further experiments so indicate it may be used as fuel.

These efforts at economy are in the early stages of development and are well worth while, but care should be taken to see that the fiber is removed from the wash water by careful maintenance and operation of the blow tanks, diffusers and blow pits.

*Screening Losses.* The pulp from the digesters, like that from the grinders, is screened. It passes first through a knotter, which removes the knots and large slivers, and later through the fine screens which remove the too coarse fibers.

These processes are almost always accompanied by a large loss of the good fiber which adheres to the coarse material, or is carried away in the wash water, and irregular cooking or lack of control of chemicals increases the amount of fiber lost.

The rejected material from these operations is sometimes refined and again screened, but as this fiber usually is discolored or is dirty from the knots and rot, the final answer is the rejection and waste of the major part.

Students of the subject state that the waste of fiber in the white water should not exceed 3 per cent of the weight of pulp nor over 1 per cent of the weight of prepared wood.

*Conversion Losses.* After the stock is screened it is ready for the paper mill. Usually, however, the mill is located elsewhere or is not ready for pulp, in either of which cases the pulp is converted into lap form and stored or shipped. In this process fiber is again lost on the cylinder which removes the water.

With the passing of the pulp to the paper mill it is found that, although there is but one place in which any loss should occur, and although the white water from this source (paper machine wet end) can be used again in the beaters, screens, etc., still there are losses or shrinkage about as follows:

| | |
|---|---|
| Wrapping-paper manufacture | 5 to 10 per cent |
| Newsprint-paper manufacture | 7 to 12 per cent |
| Tissue-paper manufacture | 10 to 15 per cent |
| Book-paper manufacture | 10 to 18 per cent |

The cause of these losses is often the use of surplus water in which fiber is discharged to the sewer with the white water. Save-alls of both the sedimentation and filtration types have been developed to a high state of efficiency (95 to 98 per cent), and they offer a solution for the white-water troubles, as well as a return in dividends. Fig. 7 shows a type of apparatus for this purpose in common use.

The items in which other wastes may occur are of an infinite variety and cannot possibly be mentioned in an article of this kind. We return, therefore, to the best solution of the problem offered to date, namely, the recommendation that time enough be given for careful study before starting the mill and the practice of eternal vigilance in operation.

## Bibliography

The following books, selected from a long list, will give a good start to any one wishing to study pulp and paper manufacture in detail:

The Manufacture of Pulp and Paper, five volumes, prepared by Pulp & Paper Technical Association.
Pulpwood and Wood Pulp in North America, by Kellogg.
Paper Making, by Cross & Bevan.
Modern Pulp and Paper Making, by Witham.
Chemistry of Pulp and Paper Making, by Sutermeister.
Text Book of Cellulose Chemistry, by Heuser, West, and Esselen.

# Lacquer and Varnish Films

## A Study Revealing a Definite Similarity of Failures, Pointing Out the Problems Calling for Research Work and Discussing the Development of a Clear Lacquer to Withstand Outside Exposure on Wood

By PAUL S. KENNEDY,[1] NEWARK, N. J.

IN A PAPER presented at the 1926 Annual Meeting entitled "A Study of Varnish and Lacquer Finishes Exposed to Accelerated Breakdown Tests," the author stated that as some of the results attained were more indicative than conclusive, the investigation would be continued. Accordingly the outstanding points of the work have since been checked and further supplemented by some normal exposures and by practical assistance from wood cabinet manufacturers. As the investigation proceeded some interesting points developed:

1 The ultimate failure of lacquer and varnish films was found to be surprisingly similar. It was positively demonstrated that these failures could be distinctly classified and recognized, and their causes clearly defined.

2 It was found that there was a general lack of understanding among those actually engaged in wood finishing as to the exact causes for these failures, and that it would be desirable to explain any basic similarity between the compounding of varnish and lacquer, and to detail the reasons for failures.

3 The comparative behavior of varnish and lacquer films indicated the desirable qualities to be incorporated in lacquer films, and suggested the lines of research to be pursued in order to overcome existing deficiencies.

4 The failure of clear nitrocellulose films, particularly out of doors, when exposed to the ultra-violet rays of sunlight, suggested the development of a filter for these destructive rays; either by a chemical agent or the development of a base other than nitrocellulose, which would give the desirable drying qualities of lacquer.

5 The failure of all nitrocellulose-base materials on outside exposure on wood suggested the development of a material to meet this condition which would have lacquer-drying qualities.

Most of these topics will be recognized by both the research man and the man of practical experience as worthy of comment. In view of the experience gained by the author through personal interviews, it appears desirable to him to present what follows in a popular rather than a too technical manner, sacrificing absolute accuracy in some cases to the end of a clearer understanding.

### 1 Fracture Failures of Lacquer and Varnish Films

The fracture failures of lacquer and varnish films may be definitely classified as (*a*) cross-checks, or temperature checks, (*b*) humidity cracks, (*c*) plasticizer or overcoating cracks, and (*d*) old-age cracks.

*a*—Cross-checks are caused in lacquer just as they are in varnish—by exposure of the films to a decided drop in temperature. In both types of film these cracks run at right angles to the direction of the grain of the wood. Fig. 1, a typical macrophotographic illustration of this failure, shows this very clearly.

The nature of cross-checks in lacquer varies with its flexibility. The more flexible the lacquer, the wider and deeper the cross-checks. The less flexible or "more gummy" the lacquer, the more closely they approximate the typical "hairline" varnish temperature crack.

A temperature crack on a lacquer film remains permanently visible. With certain types of varnish, temperature cracks apparently close up again when normal temperature is restored.

*b*—Humidity cracks are just as definite in their formation as temperature cracks. They are caused by a swelling force of the wood sufficient to break the film, and the fracture is always directly with the grain of the wood. Once a lacquer film is fractured with a humidity crack it remains as a permanent defect. With certain types of varnish such cracks often apparently close up again, when the swelling of the wood abates.

Two very excellent examples of humidity cracks are shown in the accompanying macrophotographic illustrations. One failure occurred on a straight-grained wood panel (Fig. 2); the other, on an oval-shaped grain (Fig. 3). It will be noted that in both cases the cracks follow the contour of the grain.

*c*—Plasticizer cracks, as they are termed by the lacquer specialist, or overcoating cracks, as they are designated by one familiar with varnish, are caused by a condition of case-hardening of the film. The softer underneath portion of the film exerts a pressure on the crusty top surface, which finally fractures it.

This crack is typical and resembles a hook, or a hairpin with one side broken. After the initial failure the defection continues and the hooks join up, so that in many cases a replica of a popular type of metal paper clip is reproduced. Figs. 4 and 5 show, respectively, this type of crack in its first stage and in its fully developed state.

*d*—Old-age cracks are, as their name indicates, the ultimate deterioration of a film through the simple process of wearing out. They are found more frequently with varnish than with lacquer, and while they resemble overcoating cracks to some extent, they are generally much smaller and more rounding and their inception is usually in a "crow-foot" formation. Fig. 6 is a typical illustration of the old-age crack.

### 2 Basic Similarity of Lacquer and Varnish

Basically speaking, lacquer and varnish are surprisingly similar in the way they are compounded. The popular nitrocellulose type of lacquer is composed principally of soluble cotton, gums, thinners, and plasticizers, while varnish is composed of vegetable drying oils, gums, thinners, and driers.

The plasticizer content of lacquer and the drier content of varnish can be eliminated from the consideration of the film in general, because both are present in minor amounts for incidental purposes.

A plasticizer is usually a non-evaporative liquid, which is a common solvent for gums and cotton, and its purpose is to maintain a lasting union between these two ingredients; while at the same time imparting a certain amount of elasticity to the film.

The driers in varnish are usually compounds of lead, manganese, or cobalt, and their purpose is to hasten drying by stimulating the oxidation of the oils.

Both lacquer and varnish contain thinners. Admittedly these thinners differ in their chemical composition but upon exposure to the air, in both cases, they should evaporate cleanly. Obviously they can be eliminated from any consideration of the resultant film in which we are interested.

[1] Vice-President, Murphy Varnish Co.

Presented at the National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., October 17 and 18, 1927.

The next point in common is that both materials contain gums. These gums may vary in their constitution, but their purpose is identical. In each case they are used only to give hardness, fullness, and luster. The higher the gum content in a varnish, the better its luster and fullness, and the more brittle its film. The same is true for a lacquer film.

how a material which dries so rapidly can be flexible or durable. The answer, of course, is that it is the chemical nature of nitrocellulose to have these qualities when properly deposited in a film, and that this can be accomplished simply by the evaporation of its solvents.

The physical nature of ultimate varnish and lacquer films,

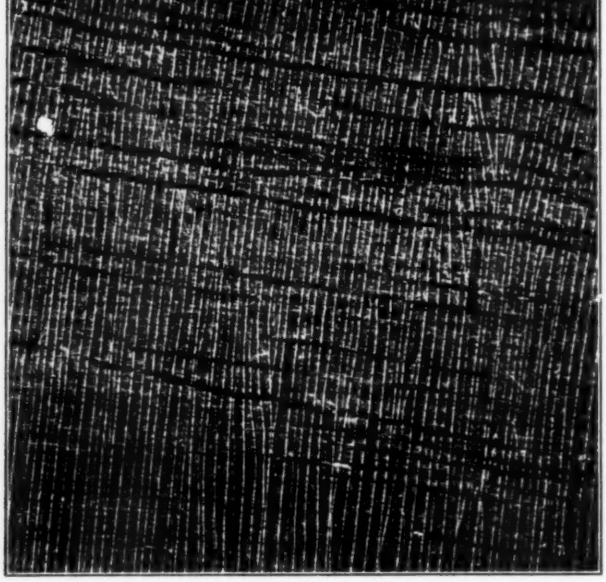

Fig. 1 Macrophotograph Typical of Cross-Checks or Temperature Cracks on Varnish and on Easy-Rubbing Types of Lacquer

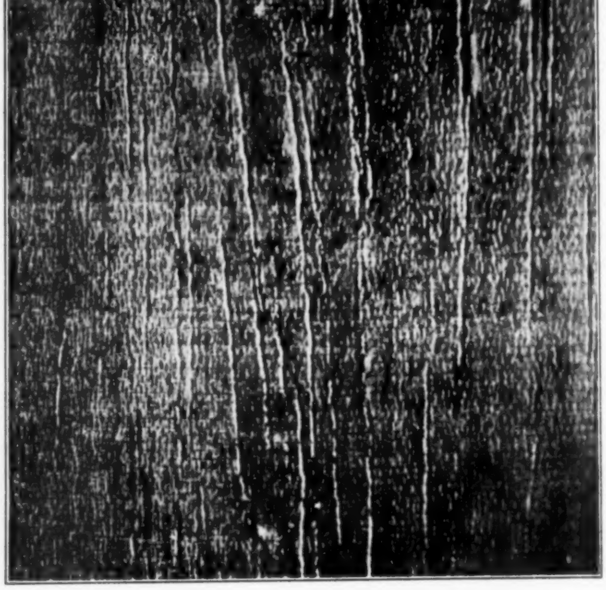

Fig. 2 Macrophotograph of a Lacquer Film Typical of Humidity Checks on Straight-Grained Wood

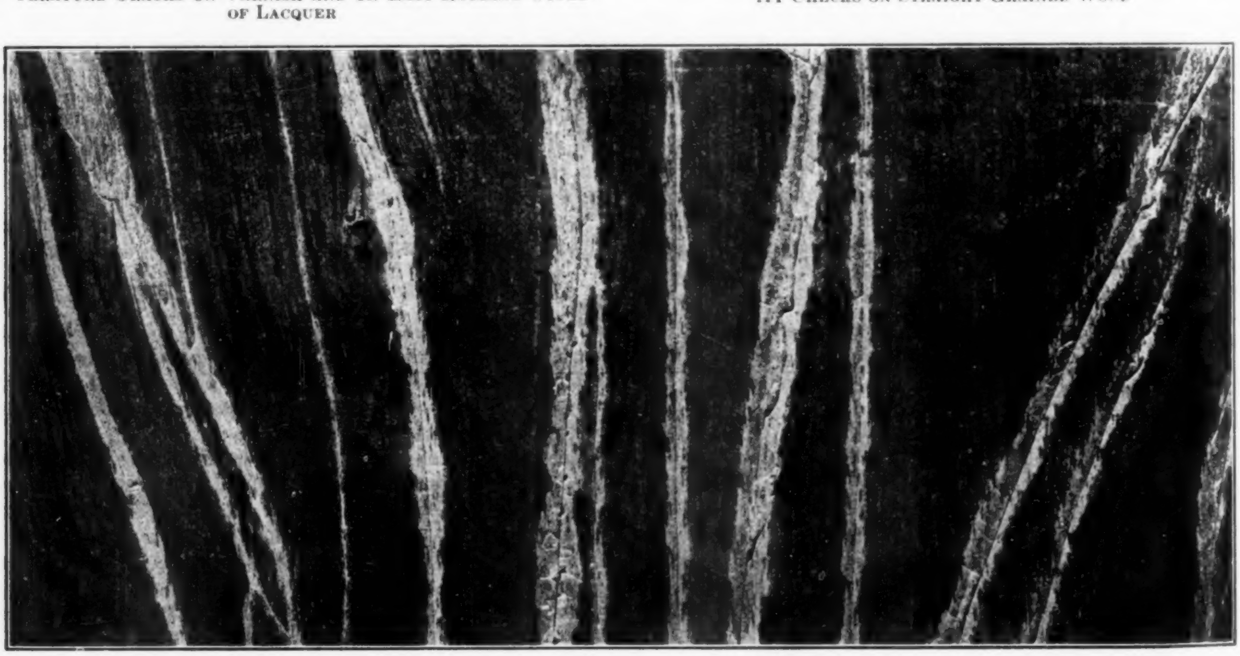

Fig. 3 Photograph of Humidity Cracks on Comb-Grained Wood Showing How Fracture Conforms with the Grain of the Wood

Hence the only basic difference between a varnish and lacquer film is that the varnish gets its elasticity from an oil which must undergo a time reaction of oxidation to produce desirable hardness; whereas lacquer obtains it from nitrocellulose which only requires the evaporation of the thinners in order to harden.

Many old-time varnish users will bring up the question as to

however, is a very vital point. A crude explanation would be that varnish dries to a "plastic" film; whereas lacquer dries to a "tight" film resembling a drum head.

Under normal conditions, a varnish film will "live" as long as it can consume oxygen. The drying of varnish is a phenomenon of combustion. As long as the oil is unsaturated or still able to

absorb oxygen, life remains. When it can no longer absorb oxygen its plasticity disappears, because it literally "burns up," and then deterioration sets in. When a lacquer film "sets" it is, to all practical purposes, dry. Actually, there is a residue of solvents in the film which gradually dissipate as the film ages. This brings up a vital point.

As oil dries it increases in weight, by the simple absorption of oxygen, and a "live" varnish film can be said to be always increasing in volume as long as it can absorb oxygen. Conversely, a lacquer film is constantly decreasing in volume, or "tightening up."

A lacquer film is much tougher, or stronger than a varnish film. If pressure is exerted on a varnish film its impulse is to yield to such force, and continue to do so up to the limit of its flexibility. On the other hand, a lacquer film will resist, and continue to do so until fractured.

With these distinctions in mind we can consider the four fracture failures previously mentioned more understandingly.

*Cross-Checks or Temperature Cracks.* Wood is quite unique in its behavior toward temperature change. Although it expands and contracts across the grain, it is immovable or stationary with the grain. When a wood surface coated with a film of finishing material is exposed to a radical drop in temperature, the film of course contracts in all directions. Across the grain the wood moves in harmony with the film; but longitudinally we have the condition of a moving film cemented on an immovable surface. If the contraction is severe enough the film must break. This is why the fracture is so clean across the grain of the wood.

As indicated in the previous explanation, when this action starts varnish yields readily, because of its plasticity, and if it be a fairly elastic type it has resilience enough, when the temperature again becomes normal, to return to its former state as far as the eye can see. The tight, resistant lacquer film is ruined, however, for it remains as a permanently visible defect.

*Humidity Cracks.* Wood is sensitive to atmospheric changes and has somewhat the nature of a sponge in its thirst for moisture at certain periods of the year. Spanning the cold, dry days of winter and the hot, humid days of summer, it is not unusual for wood to vary in moisture content from 5 to 16 per cent.

When wood is first finished, it is desirable to have its moisture content as normally low as possible. When it is able to absorb, say, 10 per cent additional moisture, the result is of course a proportionate increase in weight and volume. This results in swelling, and the movement is across the grain of the wood.

In the case of open-grained woods the "high-lights" push themselves upward, and this gives the illusion that the finishing material is sinking into the pores. It is common among finishing-material users to misunderstand this, at such time that the finishing material is "shrinking" on their work. The action is really the opposite of shrinking, and if the pushing up and outward force of the wood is sufficient to strain the finishing film, it will be fractured. Of course in this case the crack must be directly with the grain of the wood. Just as in the case of "cold-checking," the varnish film yields to this force almost at once, and even if finally fractured, in many cases, apparently "closes up" later on.

A lacquer film resists very strongly, but if the force is sufficient it snaps beyond recovery.

*Plasticizer or Overcoating Cracks.* The term "overcoating cracks" has been handed down from the old days of varnish, when linseed oil was the only drying oil available, and varnishes were very heavy-bodied and strongly charged with metallic driers.

If the varnish worker was not careful or was too lazy to brush out these hard-working varnishes, it was comparatively simple to apply such a thickness of film on the work that it would dry sufficiently hard on the top of the film to exclude oxygen from the underneath portion. The under part of the film would thus be in a more or less mushy state. As time went on, particularly with temperature changes, this difference in elasticity between the soft under portion of the film and the crusty upper surface eventually had to result in the cracking of the top surface.

With the advent of China wood oil this possibility of overcoating cracks was further increased, because it is the natural tendency of this oil to dry very rapidly and at the point of least resistance, namely, the upper surface, where the supply of oxygen is most available. This tendency of China wood oil is taken advantage of in making the so-called "crystal" or "alligator" finishes in common use on optical, radio, and electrical instruments. This commercial finish is a typical example of true overcoating cracks.

When these failures occur in lacquer they are called plasticizer cracks. Their cause is exactly the same as with varnish, i.e., the film has dried harder on the top than it has underneath. As explained above, a plasticizer is often a non-evaporative or non-drying liquid; and if a lacquer is not properly formulated, the use of an over-balanced amount of this ingredient leaves a softness underneath the top of the hardened film which must eventually result in checking upon continued exposure to heat.

*Old-Age Cracks.* These need little explanation. In the case of varnish, the complete oxidation of the oil renders the film no longer resistant to moderate torsion. In the case of lacquer it practically means inability to contract further, or a tightening down of the film.

### 3 Desirable Qualities to Incorporate in Lacquer Films

From the practical user's standpoint it would be desirable to remedy the deficient "bodying-up" or "building" properties of lacquer as compared with varnish; further, it would be obviously desirable to incorporate more of the plastic nature of a varnish film in a lacquer film.

Inasmuch as varnish possesses both of these desirable qualities, the logical thing to do would be to endeavor to amalgamate the two in such a manner that the relatively poor plasticity and the poor building qualities of lacquer would be improved by varnish, but at not too great a sacrifice in drying time.

The principal stumbling block to this, however, is the fact that nitrocellulose is antagonistic to unoxidized drying oil. But if the basic ingredient of varnish could, by a preliminary treatment, be rendered compatible or miscible with nitrocellulose, it would be a step toward solution. Through research this has been accomplished, and there is now available a lacquer with building qualities superior to those of high-gum content lacquers and of equal ease of rubbing, plus a highly desirable toughness.

This finish has the objection that it is more sensitive to abnormal conditions than straight nitrocellulose lacquer, and not as adaptable to extreme speed in coating and rubbing, day in and day out. Its dryness and hardness under normal conditions, however, are quite similar, and to all intents and purposes it is quite applicable to anything except extraordinary production schedules.

This type of "varnish-lacquer" occupies an unique position with regard to other fast-drying finishes, for in order to get the same toughness with a straight nitrocellulose lacquer it would be necessary to make a tremendous sacrifice of building qualities and ease of rubbing.

### 4 Synthetic Lacquer Resistant to Ultra-Violet Rays of Sunlight

To the finish manufacturer a "lacquer" is a finishing material which dries quickly to a hard film. Unfortunately, the popular conception of lacquer is that it is a nitrocellulose-base material. The tin decorator has been using varnish materials which bake hard in a few minutes for a great many years, and he has always called them lacquers. Then there are Chinese and Japanese

"lacquers" and also solutions of gums in alcohol which have been termed "lacquers" for years. Obviously none of these contain nitrocellulose. So when the term "lacquer" is now used here, it does not necessarily refer to a material of nitrocellulose base, but rather to almost instantaneous drying qualities.

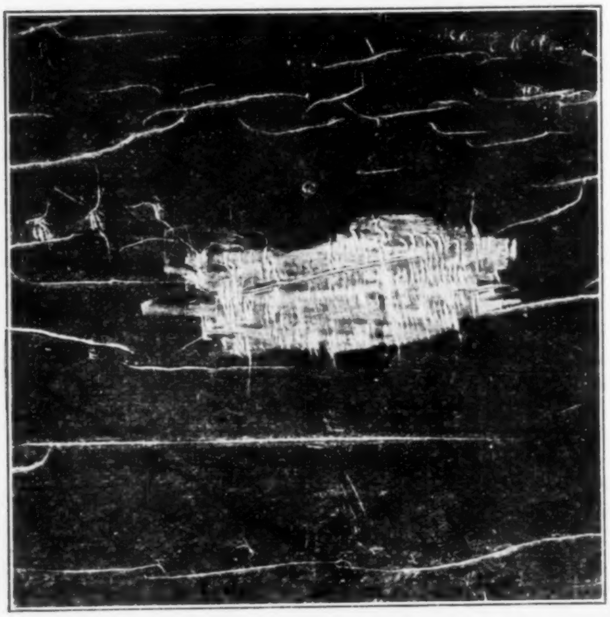

Fig. 4 Overcoating or Plasticizer Checks in Their First Stage—The Hook Check

(The large white section is a place where the film was shaved down to further examine depth of cracks.)

Fig. 5 Overcoating or Plasticizer Checks in Their Finally Developed Stage—The Loop Crack

It is well known that nitrocellulose in the clear form breaks down very rapidly under the ultra-violet rays of sunlight. Window glass is a good filter for ultra-violet rays, so the problem of durability of a clear lacquer film is an out-of-door problem.

There would be three logical solutions for this problem: First, to introduce a soluble chemical into a nitrocellulose film which would act as a filter for the rays. Another would be to partially replace the solid contents with an ingredient which in itself is a good filter, so as to partially reduce the effect. A third would be the production of an entirely foreign basic material which would deposit a satisfactory and durable film not affected by the ultra-violet rays.

Much work has been done on the first-mentioned method, but with very little satisfaction. Aniline-base ingredients have shown some promise, but the better of them discolor the film.

The second method has been employed successfully to some extent by the combination varnish-nitrocellulose type of lacquer previously commented on for wood-cabinet work, but in a more elastic form.

Vegetable oils are ultra-violet-ray filters of the best type, and the employment of a pretreated varnish in the combination has already given good results by greatly increasing resistance. At present only laboratory data are available upon which to predict ultimate results, but there is a fleet of taxicabs in New York, which have now been in service for over six months, with a coat of clear varnish lacquer over colored lacquer on their bodies, and there is as yet no sign of failure. It is believed, therefore, that this material will work out in practice much better than accelerated-weather laboratory tests would indicate.

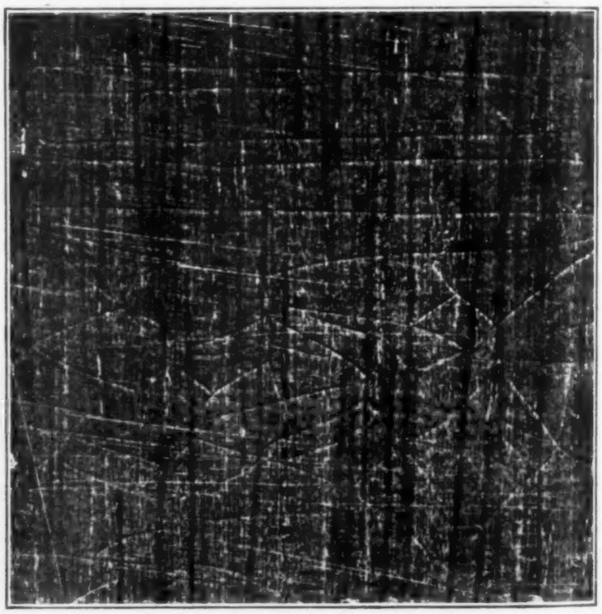

Fig. 6 Macrophotograph Typical of Old-Age Cracks

But even this promising advance for outside exposure has the disadvantage that although the endurance "on wood" out of doors is greatly improved, it is not nearly as good as that of varnish "on wood" out of doors.

This would make it necessary for the research man to develop the third-mentioned possibility, namely; a material which can be deposited in a film, will dry like a lacquer, will resist the ultra-violet rays of sunlight, and will stand up on wood out of doors at least as well as varnish does. Such a product has been developed, and fortunately it is miscible with nitrocellulose, provided it is desired to combine the two for any reason.

An idea of this material may be gained from the following: Imagine a chemical reaction for the synthetic production of amber or copal which can be arrested at a point just before hardness so that a permanent, flexible, non-sticky material re-

sults. Upon exposure to ultra-violet rays of sunlight, instead of breaking down, an exactly opposite reaction occurs. A film of this material is rendered more and more inert chemically, so that it approaches insolubility, even in solvents in which it was originally dissolved. The film gets clearer and brighter as it gets older.

Fig. 7 Panel Finished with Very Durable Spar Varnish
(Note the breaks with humidity checks at upper end. This panel was "sealed" on the back and on all sides.)

The ultimate film will be one similar to the one predicted last year by Mr. Silverstein in a very able paper—a chemical film which will be developed on the work itself.

### 5 Synthetic Lacquer Material for Work Subject to Outdoor Exposure

And now we come to the most interesting point of all to woodworkers. This synthetic material retains its plasticity permanently, so that it yields, as the most elastic varnishes do, to the severe and unequal contortions of wood surfaces.

There has never been a nitrocellulose-base lacquer in the clear or pigmented form which would stand satisfactorily on wood. Wooden panels coated with pigmented lacquer made with this synthetic material have been compared with the best automobile pigmented lacquers, at seashore points in Florida and Massachusetts, and have now had over a year's exposure. All the nitrocellulose finishes broke down in a few weeks. The panels of this base material, however, are still intact.

The greatest possibilities for such material are in the cabinet industry, for when all is said and done, strictly nitrocellulose-type lacquer does not stand up satisfactorily on cabinet work. Manufacturers have had too many instances of humidity cracks appearing on work even before it left their factory.

This promising new material would be impractical for rubbing, as formulated for outdoor service, but it is now in the stage of being proved practical for cabinet work with necessary modifications. Its promise is not so much in improvement over present types of nitrocellulose lacquers for cold-checking as it is in alleviation of the costly mischief due to humidity checking, by providing flexibility.

It is also possible with this material to build a film on work which more nearly approaches that of varnish, than do nitrocellulose lacquers of highest gum content. A comparison of Figs. 7 and 8 will indicate its wonderful possibilities. Fig. 7 shows the film result of a most durable spar varnish after six months out of doors, exposed at an angle of 45 deg., and Fig. 8 this new material exposed alongside of it.

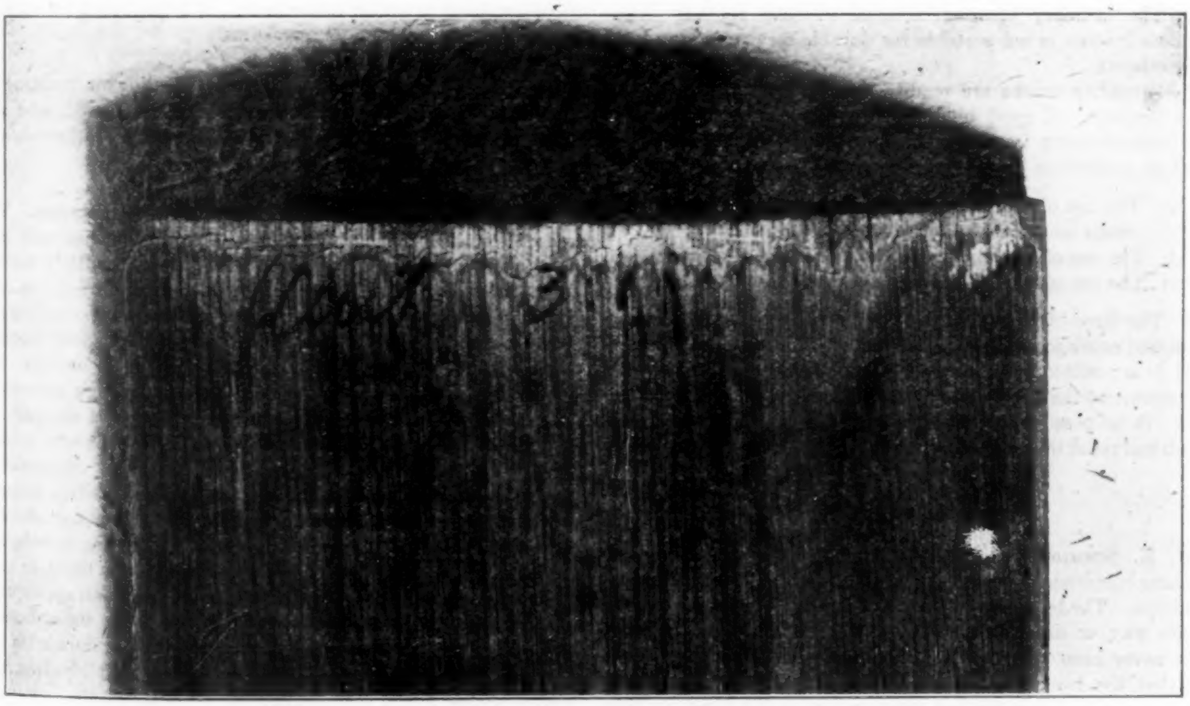

Fig. 8 Panel Finished with the Outside Lacquer, Exposed Simultaneously with Panel of Fig. 7
(Note particularly the shadow indicating the extent to which this unsealed panel warped. Note also entire absence of fractures. The ragged edge at top was caused by the slot in which panel was fitted on exposure back.)

Notice in particular that the exposure of the spar varnish is

on a close-grained hardwood—maple—and that of the new material is on a filled, open-grained wood—walnut. Also, that the spar varnish panel was sealed on the back and all sides. The new material was applied on a panel with absolutely no sealing, as is plainly indicated by its extreme warping. Its film, after this most severe test, is absolutely intact and hard as bone, despite its obvious flexibility.

The field of wood finishing with quick-drying finishes is so unscratched that these possibilities for such radical developments exist. With the problems and possible methods of solution so clearly outlined to the research man, it is not surprising that such an advance should have taken place in this relatively short period. Its further success, of course, is directly dependent upon cooperation afforded by the consumer, particularly with regard to suggesting practical refinement to the developed production.

### Conclusions

1 Varnish- and lacquer-film failures on wood are identical in so far as fractures are concerned. The same physical causes produce the same effect in each. Each type is easily and definitely recognized.

2 Varnish-film fractures may return to their original state, as far as the eye can see. Lacquer-film fractures do not.

3 A study of cracks shows them to be detectable under the microscope in approximately three-quarters of the time before they become macroscopic.

4 There is a decided basic similarity in the compounding of varnish and lacquer.

5 Varnish dries to a plastic or yielding film. Lacquer is a tight film. This is because a varnish film is always increasing in volume; whereas a lacquer film is decreasing.

6 The ordinary commercial type of easy rubbing nitrocellulose lacquer is not suitable for durable service on any kind of woodwork.

7 Humidity cracks are readily possible with nitrocellulose-base lacquers. If good building and easy rubbing properties are insisted upon, improvement for this condition in cabinet work is possible in three ways:

- *a* The use of a finish employing elastic lacquer for undercoats and varnish for top coats
- *b* The use of a combination "varnish-lacquer" product
- *c* The use of a lacquer with a synthetic plastic base.

8 The term "lacquer" should refer only to quick drying and hardness; never to the materials from which it is made.

9 It is possible to produce a synthetic lacquer material which is resistant to the ultra-violet rays of sunlight out of doors.

10 It is possible to produce a synthetic lacquer material which will resist the workings of wood, both in and out of doors.

## Discussion

W. K. Schmidt.[2] In the furniture industry the action of finishing materials is uppermost in the minds of every maker of furniture. The technical researches that have been going on in a public way or among manufacturers, chemists, and the like, have never been published for the simple reason that we have felt that the readers could not understand it. It is a pitiful admission at best, but the fact remains that such a paper as this can be understood by our practical foreman finishers.

Here in Grand Rapids we claim to have made the first nitrocellulose finish in Bissell's carpet-sweeper factory. We used cotton, ethyl acetate, and wood alcohol and made a finish out of nitrocellulose. It has been the dream of the practical foreman finisher to obtain something that would give him at once a clear solution. From the clear solution that was then obtained we were able to make a finish which was then known as "Kaiser Gray Finish."

During the World's Fair at St. Louis there was exhibited the most beautiful grade of maple that ever came to this country. We tried a year to duplicate it and finally succeeded in finding that this had a nitrocellulose finish. I have stated before that out of all of this activity in the field of wood finishes there will be evolved a new finish that has for the furniture industry the advantages of a varnish.

[2] Grand Rapids, Mich.

C. M. Bigelow.[3] Is the oxidation of varnish an advantage or a disadvantage in finish?

The Author. It is a disadvantage, because ultimately it must result in its losing its life. It is the natural procedure of its function, "breathing." When it can no longer "breathe," when the oil is saturated, we get complete oxidation and it ceases to live.

Sern Madsen.[4] Is this new synthetic lacquer applied with a brush or spray?

The Author. To all physical appearances it is the same as lacquer; it looks and smells like lacquer, because the same solvents are employed. It is therefore necessary to spray it unless especially designed for brush. I have baked it at 400 deg. for thirty minutes, and in that form have put it in boiling water and it will resist it for an hour and a half; that is the longest I have tried it, without forming any blister. It gets hard. It does not tend to soften under heat. It is produced by cooking under high pressure and temperatures.

O. M. Dunton.[5] What causes the bleeding or cracking of pigment lacquers, especially the vivid colors, as red, and also what causes the pigment lacquers to flake off on rather sharply rounded edges?

The Author. Those are both problems of formulation. The reason for the bleeding is probably the reds you had and that lake colors were employed; these colors are particularly soluble in lacquer solvents. The reason for its coming off a sharp edge is a matter of formulation, too much cotton and too little gum. Gum is quite essential to the anchorage of pigmented lacquer; cotton is not a very good adherent. Flaking is usually due, assuming the metal surface to be plain, to too high content of nitrocellulose. The first type of wood lacquer was not particularly satisfactory for the reason that you could get under a fresh film with a knife edge and strip it off. That was overcome by the addition of gum. The same thing applies to silver lacquer, where the sole object is to protect from tarnish when on display in stores. That contains practically no gum and has no adhesion to speak of, but when you come to put lacquer on brass, or anything to stand some resistance, you will have quite an appreciable content of gum, so it is really the gum that gives the adhesion and a high content of nitrocellulose is very apt to impair its adhesion. The only thing I know that will prevent bleeding is a coat of shellac mixed with aluminum. It will ruin the color, but it is the only method I know of that will be at all effective in stopping bad bleeding. Over bronze a considerable amount of gum can be put in for interior exposure.

# Improvements in Handling Methods in the Woodworking Industry

## Power-Driven Transfer Cars—Traveling Cranes for Serving Kilns—Monorail Carriers for Handling Packaged Lumber—Electric Lift Trucks—Elevators for Inter-Floor Material Handling—Disposal of Wood Waste—Various Applications of Conveyor Systems

By R. K. MERRILL[1] and G. H. RODERICK,[2] GRAND RAPIDS, MICH.

In the lumber industry, which comprises the felling of trees and their manufacture into boards or sheets of veneer, the handling methods vary greatly according to the character of the timber tracts. As several papers have been published by the Society touching on these methods, no attempt will be made here to cover that subject, and the authors will therefore consider handling methods only in that portion of the woodworking industry which starts with the purchase of boards from the lumber mills and sheets of veneer from the veneer mills, or what might commonly be called the wood-dimensioning and fabrication industry.

The methods of handling boards in the lumber yards of furniture and case-goods factories have been greatly improved during the past few years, resulting in a decrease in the number of handlings between the freight car and the dry kiln. The improved method is to load the dry-kiln cars at the freight-car door and provide yard trackage sufficient to take care of the stock of lumber, so that it is only necessary to move these cars on suitable tracks, transfer cars, cranes, etc., without the necessity of handling one board at a time. However, there still remain many lumber yards where the ground area is not sufficient, or the yard layout cannot be rearranged, to permit the carrying of the required stock of lumber on kiln cars. A manufacturer of high-grade furniture in Grand Rapids has solved that problem by acquiring a piece of land a short distance from his plant and providing a motor-truck semitrailer fitted with rails, which is used as a transfer car between the outlying lumber yard and the dry kiln at the plant.

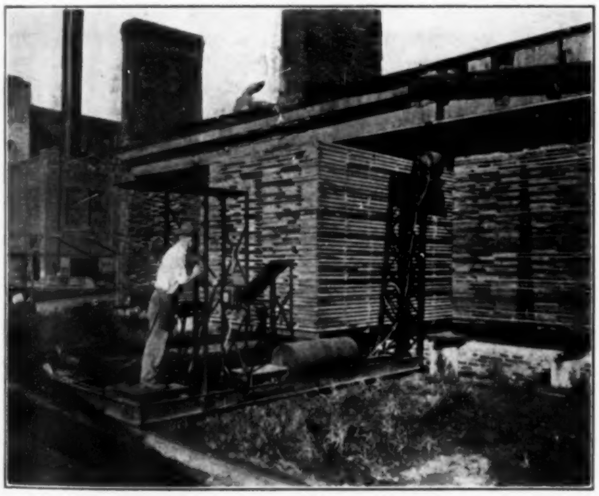

Fig. 1 Electric Transfer Car

### Power-Driven Transfer Cars

The industry has lately been experimenting with power-driven transfer cars, driven electrically or by means of gasoline motors. Each of the two types has its own field, but where possible the electric motor seems to be the more economical unit, considering power consumption and maintenance (Fig. 1). There are many locations, however, where the gasoline motor is best suited on account of the lack of electricity, but in cold climates it must be watched closely to prevent freezing in the winter time. The use of direct current is of considerable advantage in starting heavy loads as when several cars are being pushed into the dry kilns by means of the winding drum with which this type of transfer car is fitted. Where direct current is not available, the slip-ring induction motor should be used on this type of equipment. Individual motor drive on the winding drum and on the car gearing eliminates the clutch trouble experienced with single motor drive.

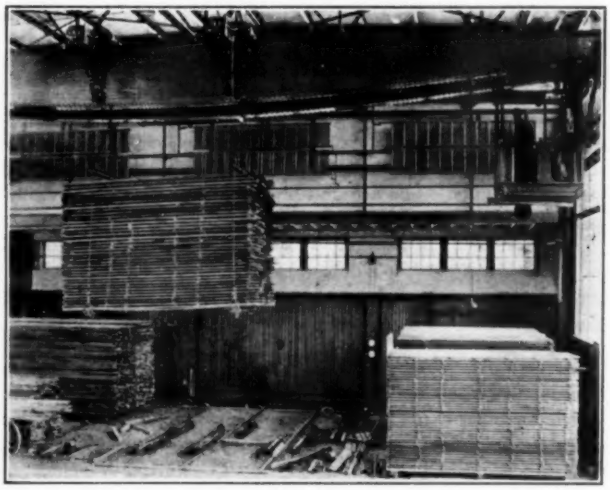

Fig. 2 Eight-Ton Traveling Crane Handling 3000-Ft. Kiln Package

### Traveling Cranes for Serving Kilns

The use of the overhead traveling crane has up until the present time been avoided by the furniture industry on account of the cost of such equipment and of the building which houses it. There are certain cases, however, where such an outlay may be necessary. A crane of this kind was recently installed by the authors in connection with the expansion of the kiln-drying facilities in a Grand Rapids plant (Fig. 2). On account of the yard layout the ten kilns previously in use could not be

[1] Chief Mechanical Engineer, American Seating Co. Mem. A.S.M.E.

added to, and due to the fact that they were "cross-piler" kilns and that it was desired to install "end piler" kilns, which the authors believe to be more efficient for drying certain varieties of lumber, the new and old batteries of kilns could not be served by the same transfer car. In addition to this, it was necessary to permit a railroad siding to run through the building. The building was designed to permit the installation of a crane having a capacity of 8 tons. This is a standard traveling crane such as is used in machine shops, foundries, the steel industry, etc. The use of one 8-ton trolley was first considered, but the problem involved in properly balancing the load, which is rather bulky, so as to prevent the possibility of tipping over endwise and spilling the boards out of the package, suggested the employment of two 4-ton trolleys controlled separately. This method has worked out very well, and loads are being transferred with considerable speed and perfect balance without the necessity for handling any of the boards by hand.

### Monorail Carriers for Handling Packages of Planed Lumber

A similar use is being made in the same plant of an electric monorail carrier for handling packages of planed boards to the cutters' benches (Fig. 3). These packages contain about 1500 ft. or less, depending upon the kind of lumber, and are brought into the building on a tractor-drawn trailer in lots of one or two packages at a time. They are placed in storage in the proper location by the telpher, and are taken from there and carried to the cutters' benches when wanted. This method has proved more economical of floor space than the use of industrial cars with a transfer car, as it allows the stock to be built higher, requires no aisle, and permits the moving of loads without the necessity for handling one board at a time. It is of course necessary that the building be constructed heavy enough to support the monorail track, but it so happens in this case that this track is installed on the ceiling of a very high first floor of what is intended to be a four-story building, so that it was not necessary to build extra strength into the floor in order to support the monorail. The average woodworking factory, unless provided with a high first story, would probably find this method somewhat difficult, particularly the older type of mill-construction buildings.

### Electric Lift Trucks

Engineers in general are familiar with the remarkable savings which have been made through the introduction of conveyors in automobile machine shops, thus cutting down what Mr. Ford calls the "handling in making." At this point it is well to remember that handling forms a larger proportion of the cost of woodworking operations than it does of most machine-shop operations for the reason that the cuts are made rapidly and in quick succession. Very often it will prove economical to use the ordinary type of factory truck so that machine operators can shift a fresh load of stock to the machines without waiting for the regular truckers, who are hired for this purpose only. However, lift trucks, both hand-operated and electric-driven, have been used by the authors with some considerable economy. The electric lift truck (Fig. 4) usually requires a larger and higher platform than the ordinary hand lift truck, but this difficulty was met by building a platform on top of a hand-lift-truck base which would handle the higher platform needed for the electric lift truck, thus providing a bridge between the two types of equipment. The electric lift truck is used generally for the long-haul and between-floor movement of material. Short pieces of cut and ripped stock are handled best on the platform type of equipment. Maintenance of floor surfaces and of trucking equipment is less where this type of truck is employed than with the old-style factory truck commonly used by the woodworking industry.

### Elevators for Inter-Floor Material Handling

In considering material-handling facilities, one should not forget the elevator for carrying material between floors. Many of the old woodworking factories are provided with the old-style belt-driven elevator which starts the load by shifting the belt. In some cases these elevators were driven from the main lineshaft, which latter piece of equipment has practically disappeared from the modern plant on account of the introduction of the electric drive. It has been the authors' experience that the most modern elevator equipment possible within the limits of the money available should be provided in woodworking plants, and that the cars of these elevators should be large enough to give plenty of room for all types of loads. It might be necessary to install cutting-up and dimensioning operations on an upper floor for some particular class of goods, and the large elevator car lends itself very well to this layout. Within the past nine years the authors have seen elevator speeds increased from 40 ft. per min. in the old plant to 150 ft. per min. in the plant completed during the present year. Changes in elevator equipment were made a few years ago giving speeds of 80 and 100 ft. per min., but even the two 5-ton elevators at 150 ft. per min. last installed do not seem to run fast enough, although they have been in operation less than a year. These two units were designed for use with the latest switching equipment and are push-button-controlled with variable voltage control. Operators are eliminated and the trucks are operated by the electric-truck operators above referred to. In the last case, crating lumber is brought in from the lumber yard by gasoline or electric tractors, placed on the elevator and carried to the fourth floor, where it is cut up by the swing saw at the crating operation. A small elevator car would have prevented such an arrangement.

### Grouping of Continuous-Feed Machines into a Conveyor System

A considerable saving in handling is possible where continuous-feed machines can be grouped together so that their chains form a part of a conveyor system. The authors have one case in mind where two double end tenoners are placed end to end with a boring machine intervening and a shaper at the outfeed end of the last tenoner. The material is fed into the first tenoner, and the man who does the handling between the two tenoners also does the boring operation as he handles each piece. The shaper men take their work from the last tenoner, and when they have finished the shaping operations, it is ready for sanding. It was necessary to synchronize the machine feeds so that work would not pile up between them. Such an arrangement means a saving in floor space and production time. The rearrangement of this battery of machines from its former location resulted in the saving of about $3500 a year due to the elimination of machine feeders alone, without taking into account the item of floor space.

The introduction of the continuous clamp carrier has resulted in a saving, and while this is considered as a machine it is actually a conveyor. Most up-to-date woodworking plants are equipped with this device. There are several good ones on the market, both hand- and power-operated, but for continuous production the authors prefer the power-operated machine in the large units and the hand-operated one for small work.

### Disposal of Wood Waste

Any discussion of the handling involved in woodworking operations also brings up the question of the best method of disposing of the wood waste caused by these operations. That this is a large factor in the power demand in a woodworking factory is

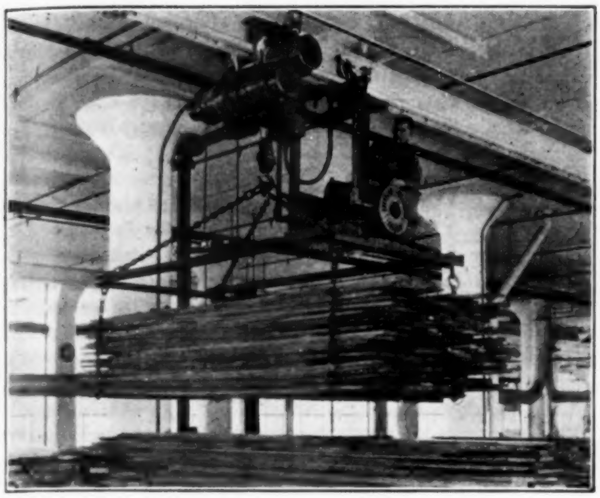

Fig. 3 Three-Ton Monorail Carrier Handling Packages of Planed Lumber to Storage and to Cutting Benches

Fig. 4 Two-Ton Electric Lift Truck Handling Wood Scooped Seats in Process of Manufacture

Fig. 5 Layout of Exhauster Fans and Dust Collectors on Roof of Woodworking Factory

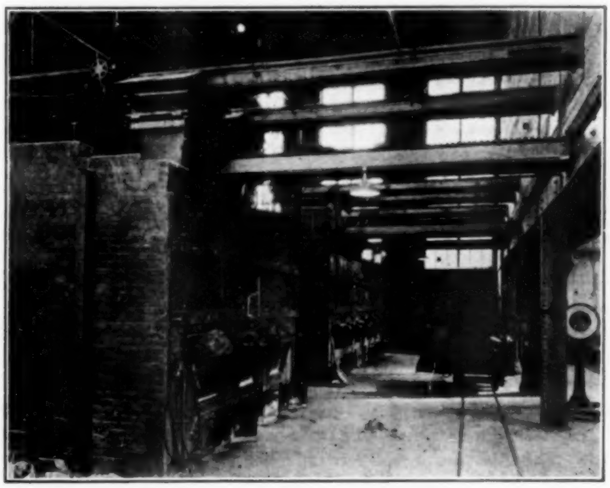

Fig. 6 Boiler Room with Furnaces Equipped with Screw Feed for Shavings and Hogged Fuel

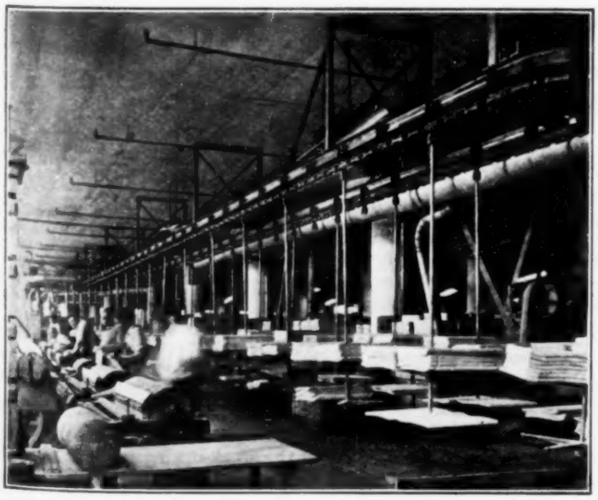

Fig. 7 Conveyor for Handling Stock Between Several Sanding and Inspection Operations

Fig. 8 Conveyor for Drying Stained Pieces

proved by the following figures. In two factories producing about the same type of goods with which the authors are familiar, the power required to drive blowers producing the necessary draft for removal of shavings and dust was 25 per cent of the total power required to operate the factory, including conveyors, elevators, hot-blast heaters, etc. This figure was exceeded in another factory, where it was about 50 per cent, due to the nature of the work performed, the cuts being very light and the proportion of air moved to weight of shavings and dust being greater. In some woodworking operations, such as flooring mills, the proportion of power required for handling shavings would be less, due to the concentration of the machining operations in a few high-speed machines. In any case it is well worth the engineer's time to devote considerable thought to the layout of these blower systems. A large factor of safety is necessary for future expansion as well as continuous performance, and also because the character of the shavings has a bearing on the amount of friction introduced into the duct system. For example, a blowpipe system, as it is called, might function perfectly on light sander dust, but would give trouble when machines producing coarse chips were connected to it. On the other hand, an overpowered system is wasteful, as it is usually necessary to operate it as a unit whether or not all of the machines connected to it are producing waste material.

In the plant with which the authors are connected, it is the custom to offer for sale all of the end cuttings from the boards. It is cheaper to do this and buy coal to replace it as fuel, since this type of material is rather hard to fire by hand and requires too much power to reduce it to small pieces. The last-mentioned method, namely, the use of a shredder for reduction of rippings, small end cuttings produced by the machining operations, and plywood scraps to a size which can be fed into the blower system, has proved economical of handling and allows this type of material to be fed into the boiler furnaces without opening the furnace doors. The furnaces are fed by means of screw conveyors feeding out of the bottom of a concrete bin where the shavings and crushed wood have been deposited. This screw feed has proved to be much more satisfactory than the older method of feeding directly out of the dust collector on top of the boiler house, for the reason that it allows the feeding to be governed automatically by controlling the speed of the engine driving the screws. A standard stoker control is used for this purpose. Excess air, which is often present when the shavings volume falls off suddenly in the factory and the fireman does not get a chance to regulate his blowpipe gates properly, is prevented from entering the boiler furnace with its damaging effect on the setting and tubes. The wood shredder is served by a standard fabric-belt conveyor similar to that used on coal, stone, etc., which brings small cuttings from the miter saws and similar machines to the shredder location. It has been found necessary to provide an operator on the shredder on account of the disastrous effects of large nuts, wrenches, and other foreign material which often find their way into the machine. Some of the material is also dumped down to the shredder location from the upper floors through a metal chute. Periodical inspection of the shredder—every six weeks—is necessary in order to dress up the hammers and grid, and keep everything in proper working order. At first it was the custom to feed used crating material, which had nails in it, through this shredder, but it was decided, after two or three experiences with fire, to burn such material by hand-firing methods where the nails could do no harm.

### Handling of Stock Between Successive Sanding Operations by Overhead-Trolley Conveyor

Where several operations are performed in succession, as in the sanding of wood parts, the overhead-trolley conveyor driven by a chain has been found satisfactory and to effect a considerable saving in floor space and handling (Fig. 7). All the machines in the layout are grouped around the chain conveyor, which has suspended trays hanging from the overhead chain. In this way quite a large group of men can be served with work without any delay and without the use of any hand trucks. After the stock has been routed and shaped, the inspector places it on the upper tray of the conveyor. The conveyor moves past the drum sanders, who remove the stock, perform their respective operations, and return the stock to the conveyor, this time on the lower tray. The conveyor then passes the spindle-sanding operation, where the stock is removed, spindle sanded, and placed on trucks to be taken to the staining operation. This conveyor dispenses with all trucking operations between routing and spindle sanding, keeps stock moving, thereby cutting down stock in process, and eliminates congestion.

The production of plywood parts involving the use of a hydraulic press, together with cauls held under pressure by clamps, has required the use of some method of storage and handling these cauls. In the furniture trade the cauls are quite large and weigh close to one ton each. It is a common practice to handle these on factory trucks. Our experience covers a period of about 15 years, during which this operation has been improved, starting out with old-style strap clamps held by steel wedges driven in by hammering, and handled on common two-wheeled warehouse trucks. The first improvement made was the substitution of a new press and clamps of the I-beam and turnbuckle-retainer type. The press was arranged with a roller unloader so that the cauls could be run out on the rollers and picked up off these rollers by means of a lift truck. The cauls were then allowed to stand during the drying period on lift-truck platforms. This change, which was made some years ago, resulted in an immediate reduction of 40 per cent in the number of men required to turn out the product, and later in an increase in the production by the reduced crew as soon as they became accustomed to the new order of things. The next step to reduce handling was the use of a roller conveyor in connection with a drag chain for removing these cauls from the press, during the drying period, and returning them to the press for reloading. This change resulted in a 25 per cent decrease in cost as compared with that obtained by the first improved method. Another arrangement, which has not been in production long enough to determine the saving accurately, is now being substituted whereby the cauls will be handled on a chain-driven overhead-trolley conveyor which is started by one of the operators and stopped automatically so that the cauls are in the right position for handling on and off the suspension hooks attached to the trolleys. This raising and lowering of the cauls is done by means of compressed-air hoist underneath the roller tables leading to and from the hydraulic press.

### Conveyors for Handling Stained Wood Parts

The finishing of wood parts offers a field for the use of conveyors. The old method of staining small parts was to dip the pieces in a tank of water stain and stack them up to dry on a drainboard. For some time past the authors have been experimenting with stain driers consisting of a conveyor chain with specially fitted links provided to hold the stock so that no marking at the contact points would be observed. The first one of these driers was a rather complicated-looking affair, having a hot blast of air traveling across the top of the conveyor table. This was done in order to avoid the possibility of having trouble with the drip of the stain, which drips off the stock during the first few feet of travel of the conveyor. However, when more room was available it was found that a rather long conveyor with only slight amount of heat worked out very much better. The pieces

are dipped in the tank and set on the conveyor (Fig. 8), which carries them over steam radiation and then underneath a blast of warm air. They are finally inspected at the end of this conveyor and the good pieces placed on a roller conveyor which runs parallel to the stain-drier conveyor but in an opposite direction. The inspected and passed pieces roll down by gravity to the operators, who apply the first coat of shellac or sealer. The introduction of this scheme resulted in an increased production by the first coaters and also allowed us to effect a reduction in the labor cost of staining of 40 per cent. A second conveyor was installed for some smaller pieces which has no heat applied to it, but the extra length of travel is sufficient so that the parts are dry enough to handle when taken from the end of the conveyor. The use of this conveyor resulted in a saving of 50 per cent in the cost of doing the work, as well as in freeing a considerable amount of floor space formerly needed for the drying operation. The adoption of lacquer finishes, which must be applied by spray guns in booths, has finally led to the intro-

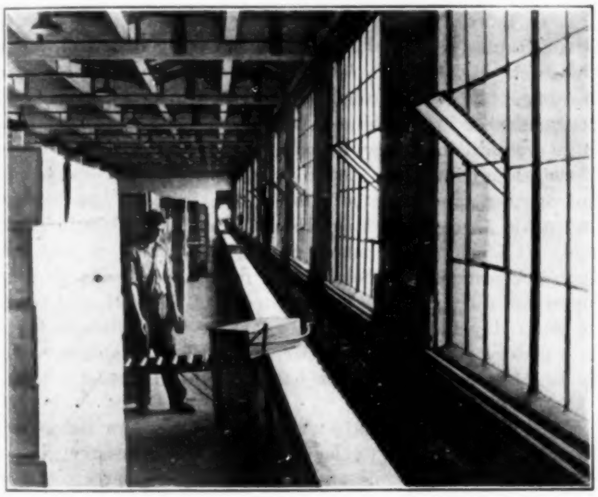

Fig. 9 View of Conveyor Feeding Cartons off to Storage Pile

duction of a conveyor for handling pieces to and from the operators at the booth. Several experimental conveyors for this work have been installed by the authors and the results of the experiments have shown that it is necessary to keep the conveyor parts covered from the action of the lacquer spray, as the lacquer tends to build up a coating on these parts and this must be removed by rather careful scraping on account of the fire hazard. The most satisfactory type at present developed by them seems to be the overhead-trolley type, driven by a chain with carriers suspended so that only the carriers pass through the booths. An unlooked-for development in connection with this conveyor was the application of a heavier coat, due to the fact that the operator could stand directly over the work. The pieces being coated in this case average about 18 in. wide × 24 in. long, and are supported on rubber-tipped wooden pegs attached to the suspended carrier. The previous experiments were conducted on a straight-line conveyor, while the last-mentioned conveyor is an endless overhead conveyor. This made it possible to place the spray booths on opposite sides of the hollow square enclosed by the conveyor trolley rail, which resulted in a 20 per cent decrease in the labor cost of handling the pieces and applying the coats below that shown by the first experimental installation.

### Miscellaneous Conveyor Applications

The use of conveyors for the assembly of automobiles, refrigerators, kitchen cabinets, etc. is well known. The authors have had considerable success with the use of an ordinary wood-slat conveyor, which forms in effect a moving bench top on which to assemble wood and steel parts. The parts are fed on to the conveyor at the proper point and the finished product is inspected and placed in the packing carton at the end of the conveyor. The carton is sewed shut and is then ready for storage and ship-

Fig. 10 Discharge End of Conveyor Feeding Cartons into Freight Car

ment. This conveyor resulted in an increase in production and a consequent decrease in cost amounting to 10 per cent. It was formerly the custom to have the trimming department do the assembly work and then handle the completed assemblies to the packing department, which put the assemblies into the shipping cartons. By rearranging this operation in connection with the conveyor, the trucking between these two departments was eliminated and considerable floor space devoted to the handling of the bulky trucks was released for other uses.

The final shipment of the product in cartons is facilitated by a belt conveyor which runs along one side of the warehouse building. This conveyor is about 380 ft. long. It also serves to carry a portion of the product from the packing operation to the storage pile (Fig. 9), and makes it possible to place the wood parts in cartons and have them go direct from the closing operation to the freight car (Fig. 10).

In general, the authors' observation in connection with the installation of conveyors has been that departmental foremen are inclined to keep operations intact, but as soon as a conveyor is installed and operations which occur in sequence although in different parts of the plant are moved together on the conveyor, this antagonism disappears. Recently, the authors built a new plant the entire second floor of which was laid out to take the operations in sequence, so that the finishing is now being done in the same room with the gluing, planing, machining, and sanding. After finishing, the assembly operations were added on the wood-slat conveyor mentioned above, so that a large portion of the material which enters this room at one end ready for gluing, leaves it packed in the shipping carton ready for the customer.

## Discussion

P. H. Bilhuber.[3] The lumber-handling system in the cutting room of the American Seating Company which we saw this morn-

[3] Asst. Factory Manager, Steinway & Sons, Long Island City, N. Y. Assoc. A.S.M.E.

ing looked to me to be rather expensive. Has the cost of this investment been figured against the labor saving effected?

R. K. Merrill. In answer to Mr. Bilhuber's question, we have been cutting 30,000 to 32,000 ft. of lumber a day using this method. The other method of handling, using kiln bunks, transfer cars, etc., would have required more floor space than we had available in that location, and we decided to adopt the present method after figuring up the cost of the installation, which I believe was about $4500. The monorail track is close to 500 ft. long, and the hoist has a capacity of 3 tons.

Charles Kindel, Jr.[4] Can Mr. Merrill tell something of the method used by his company in reclaiming lacquer? I understand that as much as 10 per cent is being recovered.

R. K. Merrill. I did not mention the subject of reclaiming lacquer because this is a conveyor paper, but since using the conveyor, we have started to reclaim a portion of the lacquer. Lacquer is quite expensive, and if it can be reclaimed there is just that much more for the next day's use. We find it is not damaged. It is necessary, of course, to add thinner. I believe we are reclaiming on this particular conveyor mentioned a quantity of lacquer amounting to about ten per cent of the day's use. This is reclaimed by having detachable plates in the bottom and at the back of the booth, which can be removed and immersed in the thinner tanks. Every conveyor we build seems to us to be better than the one before, and it often happens that it is quite different, because we get ideas from one conveyor which we incorporate in the next. We have in mind another spray booth and lacquer conveyor system to be installed, operated entirely differently from the one described, with the reclaiming feature incorporated in the booth.

Arthur Koehler.[5] One interesting feature is putting the pieces through the drier after they have been dipped in the stain. We think that this operation requires considerable attention. If the water stain or the water used in sponging to raise the grain remains on the wood for any length of time and gets a chance to soak in, and it does not have to soak very far, it is apt to cause trouble. We believe some of the fine checks we get in finishes are due to that very thing. This may require a little explanation. If the surface of a dry board becomes wet, it tends to swell. The wet region does not extend very far inward and the whole board will not swell because the inside does not get wet. Therefore the surface cells, in trying to expand, become permanently crushed, so that when the surface dries out again, as it will, the cells will shrink away from each other and produce fine checks. Just how serious that is in wood finishing I do not know. The water should be dried off as rapidly as possible after it is applied, because it is only necessary to wet the surface.

R. K. Merrill. We agree with Mr. Koehler's contention, and of course the application of water immediately after the planing operation has always been a bugbear with us. We have in mind a conveyor to handle these peices, and in this new location the conveyor can be attached to the ceiling and carry for quite a distance without interfering with anything.

Burritt A. Parks.[6] Our line is more particularly connected with the power plant, and consequently I am more interested in conveyors supplying refuse to boiler furnaces. In one plant which we installed recently, we used a little different scheme for automatically conveying refuse to the boiler furnaces. We use a Dutch-oven furnace similar to one at the American Seating Company. We convey the shavings and sawdust into a shavings bin similar to the old type of shavings bin, and out of the bottom of that bin we take the shavings into a screw conveyor, which empties or discharges into a fan. The fan discharges through the roof of the boiler house into another separator and is carried thence into the furnaces. Automatic control is provided. Taking the shavings and sawdust out of the bottom of the main shavings bin allows us to reduce very materially the excess air discharged into the furnaces. As to whether that particular scheme is more efficient or not than direct feed into the furnaces, I cannot say without making a comparative test. I dare say there would not be much difference between the two. Both of the schemes practically accomplish the same object, and that is to feed the shavings and sawdust to the furnaces in accordance with the demand for steam, and also to get rid of excess air.

T. D. Perry.[7] I only wish it were possible to bring back to Grand Rapids, as we did some years ago, my good friend, Frank Gilbreth. Mr. Gilbreth was here, I should judge, nearly ten years ago, and went through some of the furniture factories. If you remember Frank Gilbreth at all, you will know that he was quite dramatic in the way he expressed himself. He went to one of the leading factories—not, by the way, Mr. Merrill's factory, but another—and after he came out he took his handkerchief and made an excellent stage imitation of profuse weeping and said, "If I could only have for mine the amount of time and energy consumed in these plants in Grand Rapids, pushing boards in and pulling them out." If Mr. Gilbreth could only be here today and see the changes that have been brought about in a factory administered as Mr. Merrill has administered his, he would have no cause for the use of that handkerchief.

Sern Madsen.[8] In 1916 when we built our new factory, we found that in addition to the shavings it was necessary to burn 3700 tons of coal in one year. We then designed a conveyor system to remove shavings from underneath the bins. It serves 4 boilers and has one motor with automatic control. The first year we saved 2700 tons of coal by cutting out excess air and getting fuel into the boilers when we needed it. I have been interested since that time in watching a number of other plants put in some sort of system for boilers controlled by steam pressure, and greatly amused in seeing how some of these plants are put in. I know one in particular, where two boilers are fired. There are two stoker engines, two extra bins, and two conveyors for each boiler, in addition to a fan to blow the shavings, and three or four electric motors. We have four boilers and do it all with one motor and one conveyor. They get results all right, but I have always wondered why they use so much equipment when there is a shorter method of doing it. There is always a possibility of simplification in installing any conveyor system.

There is one method of conveying which has not been mentioned. I refer to overhead cranes for handling rough lumber in long lengths. There is also another tool, developed in the last few years, a type of carrier that runs considerably like a hen with a brood of chickens, and one man with one of these affairs will handle as much as 80,000 ft. of lumber a day, and do it easily. This truck will go anywhere that there is a cement or plank runway. I am not so sure how it would work out in a furniture factory, but it does work in a sash-and-door factory.

# Static Loads upon Bus Bodies

## A Report of Tests Made to Determine the Static Loads Due to Interaction of Body and Chassis upon Which It Is Mounted, and a Description of the Methods Employed

BY CHARLES B. NORRIS[1] and JOSEPH A. POTCHEN,[2] GRAND RAPIDS, MICH.

THE STATIC loads upon bus bodies can obviously be divided into two groups: those due directly to the weight of the passengers and those due to the interaction of the body and the chassis upon which it is mounted. The latter loads occur at the points of fastening of the body to the chassis, and are usually indeterminate because of the multiplicity of these points. It is the purpose of this paper to point out the importance of these loads and to suggest a physical or experimental method by which they may be determined.

The usual bus-body design provides posts between the windows, spaced at intervals of 30 to 40 in.; longitudinal members fastened to the tops and bottoms of the posts and extending the full length of the bus body; and other longitudinal members fastened to the posts just above and below the windows and extending the full length of the bus body upon the left side and between the front and rear door upon the right. The rectangular spaces formed by this framework above and below the windows are paneled with some suitable material. This paneling is an effective cross-bracing and gives the body great stiffness.

The usual chassis-frame design provides two longitudinal members (usually of channel cross-section) fastened together by several transverse members. The longitudinal members are usually from 4 to 6 ft. apart and are overhung by the bus body. The bus body is usually supported at the foot of each post by short transverse cantilever beams or "outriggers" which are securely fastened to the longitudinal members of the chassis frame.

From an examination of the design one would suppose that the outriggers were intended to carry that part of the passenger load placed above them. This intention is realized only if the stiffness of the bus body is small compared to that of the chassis frame. A design fulfilling this condition does not seem practical. Either the chassis frame would have to be extremely rigid or the bus body would have to be very flexible indeed.

Josephs[3] has lately pointed out several objections to both of these conditions. He also mentions that general practice in bus-body design is quite contrary to them, the stiffness of the average body being about six times the stiffness of the chassis frame upon which it is mounted. Evidently the above intention is not realized in the average bus. The passenger load distributes itself among the outriggers in a way determined by the elastic properties of the structure. Usually the chassis frame acts as a beam supported at the wheels. The bus body rests upon this beam and extends over the rear support but does not reach the front support. If all outriggers are removed except those over the rear wheels and those at the front edge of the body, the problem becomes a very simple one. The chassis bends concave upward because of the load placed upon it by the front edge of the bus body. The bus body also bends slightly concave upward due to the passenger load within it; but the body has so much more stiffness than the chassis that its curvature is much less than that of the frame. Thus the vertical distance between the chassis frame and the body near the center of the body is greater when the bus is loaded than when it is empty. If the outriggers which we have assumed removed were left in place they would tend to hold the chassis frame at a constant distance from the body throughout its length, and therefore some of the fastenings would necessarily be in tension. The chassis frame would be pulling downward upon the body at these points.

Two methods of overcoming this difficulty suggest themselves. The bus may be designed like the old two-wheel cart. The engine and front wheels take the place of the horse, and the rear wheels carry the entire passenger load. The bus body and the chassis frame both bend convex upward due to the passenger load. If the body is six times as rigid as the frame the outriggers near the fastenings of the rear spring carry about six-sevenths of the passenger load, the rest being distributed among the remaining outriggers. The second method is more unusual and has only lately been adopted by a few builders. The bus body is extended the full length of the chassis and the engine is mounted somewhere under the body instead of in front of it. In this case (assuming again that the body has six times the stiffness of the chassis) six-sevenths of the passenger load is carried by those outriggers near the spring fastenings of both front and rear springs; one-seventh of the load being divided among the remaining outriggers.

Even if the above methods are employed one cannot be sure that the loads upon all the outriggers are downward unless the ratio of the stiffness of the body to that of the chassis frame is the same at all transverse sections of the bus. This condition is difficult to meet because the door openings, etc. cause a variation in the stiffness of the body, and the change in the cross-section of the longitudinal members causes a variation in the stiffness of the chassis. It seems best to design with this condition in mind, build a sample body, and determine from it the actual reactions between the body and the chassis. If some of the outriggers are found to be pulling downward upon the body they can be removed and the bus retested to determine the result. If several of the outriggers are found to be pulling downward upon the body and only a few supporting it, the removal of these few may reverse the load upon the remaining outriggers and distribute it more equally.

The method of test proposed by the authors consists of two steps: first, a test upon the sample bus, and second, a physical analysis of the data obtained. In the test upon the bus, attention is focused upon the longitudinal members of the chassis because their strength properties are usually known. The test consists of noting the changes in the deflection curves of these members due to the application of the passenger load. The points of application of direct loads to these members, such as spring fastenings, outriggers, etc., are noted and recorded. At least one deflection reading is taken for each load close to but not necessarily at the point of application of the load. The greater the number of points at which deflection readings are taken and the more uniformly they are distributed along the longitudinal member, the more nearly accurate will be the determination of the loads.

A physical analysis of these deflection data may be obtained by loading a model beam in such a way that its deflections are proportional to the deflection readings taken from the longi-

[3] L. C. Josephs, Jr., Engineer International Motor Co., "The Design of Motor-Bus Bodies," *Mechanical Engineering,* Mid-May Number, 1927, vol. 49, no. 5a, p. 510.

Presented at the National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., October 17 and 18, 1927.

tudinal members of the chassis. This analysis is first applied to the data taken upon one of the longitudinal members and then to the data taken upon the other. The model beam should be made so that the ratio of its stiffness to the stiffness of the longitudinal members of the chassis is the same for corresponding sections. Also the loads should be applied to the model beam at points corresponding to the points of application of loads upon the longitudinal members. The loads obtained in this manner are proportional to the loads upon the longitudinal members of the chassis frame due to the application of the passenger load. Therefore if the total passenger load used in the bus test is known, the loads upon the chassis can be determined from the loads upon the model beam by a simple proportion.

Let us now consider some data taken in a test upon a bus of the two-wheel-cart design. The test was made at the factory of the Lang Body Company upon a bus of their manufacture. The privilege of making this test and the assistance rendered by the personnel of the company are greatly appreciated by the authors.

The bus was run over a pit in the factory, and a heavy wooden beam extending its full length hung under it. This beam was supported by wires fastened to the chassis at the front of the front springs and at the rear of the rear springs. Transverse beams were fastened to it. These beams supported arms at their ends which held Ames dials against the under surface the longitudinal members of the chassis. Sand bags were used for the passenger load. The deflection data obtained are shown in Table 1.

TABLE 1 DEFLECTIONS OF THE LONGITUDINAL MEMBERS OF THE CHASSIS FRAME

DEFLECTIONS OF LEFT SIDE, IN.

| Distance from front, in. | 0 | 55 | 92 | 130.5 | 180 | 220.75 | 286.5 | 306.5 |
|---|---|---|---|---|---|---|---|---|
| Load in lb. | | | | | | | | |

The model beam used by the authors was made of poplar veneer $^1/_4$ in. thick and one-fourth the length of the longitudinal members of the bus chassis. Its width varied in such a manner that its stiffness at any section was proportional to the stiffness of the longitudinal chassis members at a corresponding section. The loads were applied to this model beam by means of twine and rubber bands. Fig. 1 is a photograph of the apparatus used. A sheet of drawing paper upon which the deflections of the longitudinal members of the chassis frame were plotted was fastened to a blackboard. The model beam was held in front of this paper by twine and rubber bands as shown. The tension upon the rubber bands was varied until the model beam was made to conform to the plotted deflection curve of one of the longitudinal members. The length of each of the rubber bands was then recorded and the test repeated for the other longitudinal member. Subsequently the forces applied by the rubber bands were determined by loading each band separately with gram weights so that the recorded length was again obtained. These weights corrected for the deadweight of the model beam are given in Table 2. The loads upon the chassis frame due to the passenger load can be determined from these weights by the following simple proportion:

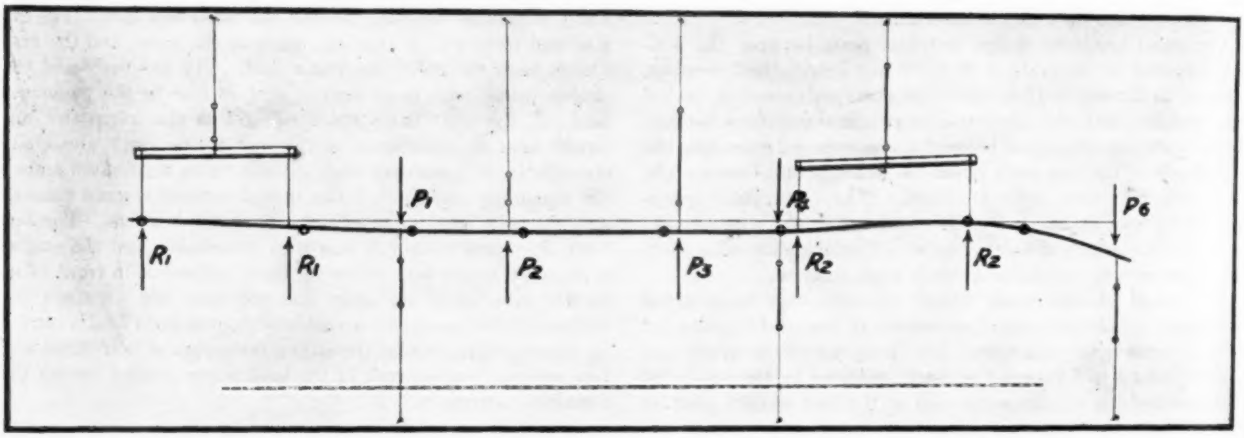

FIG. 1 MODEL BEAM SUPPORTED AGAINST DRAWING PAPER ON WHICH DEFLECTION WERE PLOTTED

$$\frac{\text{Load at specific point on one of the longitudinal chassis members}}{\text{Half the passenger load}} = \frac{\text{Corresponding load upon the model beam}}{\text{Sum of those loads upon the model beam which correspond to the loads applied by the bus springs to the longitudinal chassis member}}$$

The right-hand member of this proportionality is expressed in percentage and shown in Table 2. For convenience in computing the loads upon the chassis, hălves of the values of the left-hand members of the proportionality are expressed in percentage and given in Table 3 with a tabulation of the actual loads upon the chassis due to a passenger load of 5280 lb.

These loads were plotted graphically together with their shear and bending-moment diagrams and also the deflection curves obtained in the test of the bus. It was noted that the bus is a good example of the two-wheel-cart type. The front springs support very little of the passenger load, the rear springs taking nearly all of it. Yet it will be noted that the bus body is pulling upward strongly upon one of the outriggers located near its center on the left-hand side and bearing down heavily upon the next outrigger to the rear. Also the outrigger just to the rear of the rear spring is not carrying any of the load. If the first-mentioned outrigger were removed the second one would probably not bear down so heavily, and the third might help support the passenger load. Another test with the outrigger removed would determine this. The shear and moment diagrams are

interesting in connection with the chassis design, but give little information concerning the body.

The authors realize that this is not a complete paper but only a beginning of a practical analysis of the stresses encountered in bus bodies. They hope that it will give a slight impetus to the best engineering thought upon this subject.

An examination of these data shows that a hysteresis effect exists, i.e., the load-deflection curve taken with increasing loads is not identical with the curve taken with decreasing loads. Correction was made for this effect by averaging the deflections at each point taken at the same load. The results of this correction are in Table 1.

The data in Table 1 give three elastic curves of the chassis frame for each side of the bus. The deflections at the 1920-lb. load and the 5280-lb. load were reduced to equivalent deflections at 3600 lb. by multiplying them by the ratio of the loads. The three sets of deflection data were then averaged and the probable error of the mean computed. These data are given in Table 6.

The actual data taken are shown in Table 4. These readings were not all taken in the same test. The deflection apparatus was placed under the left side of the bus, the loads applied, and the readings taken. The apparatus was then placed under the right side of the bus, the loads applied again and the readings taken. It will be noted that some of the deflections became negative as the load was released. The authors have reason to believe that the deflection apparatus was sinking slowly during the tests. The apparatus for the test upon the left side was set up late in the afternoon and the test run the next day. It was noted that the apparatus had dropped away from the bus slightly and had to be readjusted. The apparatus for the test upon the right side was set up in the morning and the test run in the afternoon. The data show that the apparatus dropped considerably during the test. The data were corrected for this error by distributing the total drop at each deflection point evenly over the deflection readings taken at that point. The result of this correction is shown in Table 5.

The average deflection readings shown in Table 6 were analyzed by the experimental method outlined in the body of the paper. The deflection curves were plotted to scales which made the maximum deflection about 3 in. Small steel open rings made from screw eyes were used to connect the rubber bands to light silk fish line which in turn was fastened to the model beams and to nails driven into the blackboard (see Fig. 1). A sufficient number of rubber bands was used at each load point to keep the maximum elongation under $2^1/_2$ times their free length. A bright electric light was placed in front of the blackboard about 25 ft. from it. The rubber bands were adjusted until the shadow of the beam coincided with the points plotted upon the blackboard. It was found more convenient to measure the length of the shadow of the rubber bands than to measure the bands themselves. These measurements were made to the nearest hundredth of an inch.

The rubber bands were released from the model beam and each group loaded separately by means of a scale pan and gram weights. This apparatus was also supported in front of the blackboard and the

shadow of the group of rubber bands again measured. It was noted that when a group of bands was loaded the deflection increased for a few minutes after the load was applied, but finally became constant. Therefore care was taken to allow the bands sufficient time to adjust themselves to the load. The whole process of loading the model beam and determining the forces was repeated four times for each side of the bus. After each the model beam was reversed so that the curvature at each point would be in the opposite direction. After these readings were taken the model beam was cut at points midway between the load points and these sections weighed. The loads obtained corrected for both the weights of the beam sections and the weights of the steel open rings are shown in Table 7. It will be noted in Fig. 1 that the apparatus was arranged so as to give the correct ratio of load at the points corresponding to the spring fastenings. This ratio is determined by the dimensions of the springs.

An idea of the accuracy of the average results was obtained by comparing the sum of all the upward forces to the sum of all the downward forces. These two sums should be equal since the model beam was in equilibrium. The comparison is given at the foot of Table 7. Tables 2 and 3 were obtained directly from Table 7.

## Discussion

S. Madsen.[3] This test evidently has been applied to only one type of bus body. Do these calculations apply to other automobile bodies such as moving vans? To get proper stiffness in bus bodies, are wood and steel used in modern construction?

Charles B. Norris. The calculations in the paper are confined to one bus body; not alone to one type, but to one particular body. However, the same method of calculation could be applied by any bus-body engineer to any type of bus body.

The method is of value where, because of its depth, the body is very stiff, and where, because of complicated design, it is difficult to compute the elastic properties of the body and therefore difficult to determine the distribution of the forces upon it. However, the method is applicable to the analysis of any body supported upon a chassis of known elastic properties.

As to types of construction, the bus industry is in a rather chaotic state. There are buses of all kinds. One type of bus is built entirely of aluminum in which there is no chassis at all. The chassis is built into the bus body itself with regular bridge construction. There are types of metal bus bodies built of small T-sections, and depending upon the side paneling for rigidity. The panels are made of steel, aluminum, plywood, and plywood covered with steel. Other bodies are built entirely of wood with the members glued and screwed together.

# Investigation of the Pulp and Paper Industry in the State of Washington

By BRUCE WALLACE ROSS[1] and SEICHI KONZO,[1] SEATTLE, WASH.

*In this paper the authors discuss the pulp- and paper-manufacturing industry as it is conducted today and show that, owing to location, source of supply, water supply for both power and process, labor, etc., the state of Washington presents many attractions to the prospective plant builder.*

*Of the subjects taken up, the first has to do with the materials used in the manufacture of paper. Then the several species of woods found in the United States, with particular emphasis on the state of Washington, are discussed, together with statistics concerning quantities available. One of the sources of supply mentioned is mill waste, and the possibilities of carrying on pulp operations in co-operation with saw-mill activities are discussed.*

*Pulp-making processes also are treated, those receiving attention being the mechanical process, the soda chemical process, the sulphate process, and the sulphite process.*

*The process of making paper is touched upon, but owing to the fact that complete treatises on this subject may be obtained without difficulty, little more than a brief review is given.*

*Interesting statistics on the consumption of wood pulp, its production in the United States, particularly in Washington, and its exportation appear in the paper.*

AT PRESENT there is a wide-spread belief that the paper of the future will be made of some material other than wood pulp. From time to time there have been discoveries, or rediscoveries, of other paper-making materials, but in each case there has been present some factor which has prevented the marketing of the product on a basis competitive with that of paper made from wood pulp. The two principal reasons are the cost of production and the source of raw materials.

### Materials Used in the Manufacture of Paper

A good, strong, high-grade paper is made from linen and high-grade cotton rags, and is used in the manufacture of book and stationery paper. But even in the case of this paper, probably the strongest competitor of that derived from wood pulp, it has been found to be more advantageous to add a portion of wood pulp to the raw material. The raw material is anything but abundant, the United States being largely dependent upon foreign countries for its supply. The lower grades of cotton rags are used in the manufacture of building felt and sheathing paper. Manila stock is used in the manufacture of a strong, tough, fiber paper demanded by heavy products, such as containers for cement, etc. Since the World War, cotton linters have been used in the manufacture of book paper, but this has been done to supplement the rag supply rather than to enter into active competition with the wood-pulp product. Straw has entered into the paper industry to a considerable extent in the manufacture of corrugated boards. Bagasse, kelp, corn stalks, the fibrous waste from other industries, together with a long list of plants, have been tried for paper, as have even the soft and fibrous minerals. The use of these different materials in the manufacture of paper has increased with the passing of time, but in no way has their increase kept pace with the increase of wood pulp. In practically every case the production cost has been made the deciding factor in the determination of the feasibility of manufacturing the raw material into paper. Seasonal crops and the relatively low yield per unit of pulping material have, along with the transportation and storage problem, been influential in the abandonment of these fibrous materials as possible sources of supply for paper manufacture. Despite the fact that wood is a comparative newcomer in the pulp world, it is almost certain from past experience and present knowledge that it will be the predominating factor in the future pulp and paper industry. Furthermore, the paper industry has become accustomed to handling wood-pulp paper, and paper from other materials would not be readily accepted.

### Species and Quantities of Wood

*In the United States.* The area of forest land in the United States has in the past three centuries decreased from some 822 million acres to approximately 470 million. There is no way of determining the actual quantity of pulp-wood timber which is now standing, as this quantity varies from month to month, and in the newer parts of the country is more or less dependent upon the lumber industry, fires, etc. In 1870, only a little over fifty years ago, there was no material amount of wood used for paper pulp.

The United States, with respect to the timber supply, is generally divided into nine groups of states: the New England States, the Middle Atlantic States, the South Atlantic and Gulf, the Lake, the Central, the Lower Mississippi, the Rocky Mountain, and the Pacific Coast States. The total standing pulp species in million cords in each of these groups is shown in Table 1.

TABLE 1 QUANTITY OF STANDING TIMBER IN THE UNITED STATES BY REGIONS

| Region | Total standing pulp species in million cords |
|---|---|
| New England | 166.9 |
| Middle Atlantic | 162.9 |
| Lake | 330.8 |
| Central | 241.0 |
| South Atlantic | 611.5 |
| Lower Mississippi | 678.0 |
| Rocky Mountain | 442.7 |
| Pacific Coast | 897.4 |
| Total United States Proper | 3530.9 |
| Southeast Alaska | 167.0 |

The above figures do not contain the allowance for reduction in stand by the spruce bud worm, which amounts to 40 per cent, or about 27½ million cords in Maine.

The future supply of pulp wood depends almost entirely on the amount and success of reforestation, which is at present undergoing intensive study by the Federal Government, by the different state governments, and by the timber-owning private firms. At present the Southern States have the greatest stand of timber suitable for the manufacture of pulp, having an estimated quantity of about 1250 million cords. The Pacific Coast States have the next greatest amount with an estimated cordage of 850 million, while the Rocky Mountain States have an estimated 400 million cords. Each of the remaining state groups have less than 200 million cords available. In the Middle Atlantic States there has been a gradual depletion of the supplies of pulp timber, as in the New England and Southern States, and from present aspects it will be but a short time until the

[1] Department of Mechanical Engineering, University of Washington.

Presented at the Seattle Meeting, Seattle, Wash., August 29 to 31, 1927, of The American Society of Mechanical Engineers.

production of pulp will have to be curtailed, some new pulping process developed for species not now used, or some means found of speeding the second-growth timber.

At the present time there is a temporary stimulus to the use of the better grades of timber for the pulp industry in the Eastern States, due to their inability to meet the market price of the western Douglas fir in the sawmill market. It is possible under existing conditions for the West Coast lumberman to deliver his products on the Atlantic Coast at a lower price than the Eastern lumber manufacturers can. This has resulted in a condition whereby the pulp industry in those localities receives the timber that would ordinarily be routed to the lumber mills.

*In Washington.* It is only natural in the carrying on of the pulp and paper industry that as the resources are exhausted the manufacturers will turn to the locality with the greatest stand of spruce, fir and hemlock, since 78 per cent of our requirements depend upon these species; and it is especially advantageous to enter into a virgin timber country which can support the industry while reforestation is going on. Alaska and the Pacific Coast States offer exceptional opportunities in this respect. At the present time the Government is offering every inducement to manufacturers to establish the industry in Alaska, assuring them of pulp timber at a reasonable cost as far ahead as 1942.

The Pacific Coast States offer innumerable inducements for the establishment of the industry. Washington, Oregon, and California are the three states of the Pacific Coast group, and they possess about one-half of the remaining saw timber in the United States. They have about one-fourth of the stand of pulp species, in cords. Some sources of information state that one-half of the remaining virgin forest of the United States is in the vicinity of Puget Sound, and give the stand of Douglas fir alone in a belt 100 miles wide and 350 miles along the coast as 960 billion feet. Table 2 gives some interesting figures on the species of timber west of the Rocky Mountains.

TABLE 2 SPECIES OF TIMBER WEST OF THE ROCKY MOUNTAINS ACCORDING TO THE 1920 FOREST SERVICE REPORT

| | Million bd. ft. |
|---|---|
| Douglas fir | 558,571 |
| Western yellow pine | 183,453 |
| West-Coast hemlock | 94,000 |
| True firs | 82,479 |
| Redwood | 72,208 |
| Western red cedar | 49,000 |
| Miscellaneous varieties | 44,914 |
| Sugar and western white pine | 38,483 |
| Sitka spruce | 13,355 |
| Lodgepole pine | 4,566 |
| Total | 1,141,031 |

The timber in California differs in species from that in Washington, and the available quantity is somewhat smaller. The total stand of timber in Oregon is greater than that of Washington, but the percentage of pulp species is smaller, and due to the development of the country the available timber in Washington greatly exceeds that of Oregon. Table 3 is interesting in this connection. With the exception of one year, the volume of lumber cut in Washington has exceeded that of any other state since 1905, which has resulted in the greatest advancement of logging operations found anywhere in the world.

TABLE 3 TIMBER STAND BY SPECIES IN THREE WESTERN STATES

(From 1923 report of the Senate Reforestation Comm.)

| Species | California | Oregon | Washington |
|---|---|---|---|
| Western yellow and white pine | 77,176,000 | 75,549,759 | 13,731,367 |
| Sugar pine | 31,928,000 | | |
| Douglas fir | 39,114,000 | 245,797,056 | 135,860,853 |
| Redwood | 70,000,000 | | |
| All others | 66,287,000 | 74,429,414 | 133,053,262 |
| Totals | 284,505,000 | 395,776,229 | 282,645,481 |

When it is considered that one-fourth of the remaining pulp wood is in these three states and that Washington has more than her share of this commodity, considered with the fact that the timber stand is more localized in this state than in others, the wonderful possibilities of the development of the pulp industry in this section of the country are realized. Some sources of information give the fact that in most parts of the country the average cut of pulp wood is five cords per acre, while that of western Washington is in the neighborhood of 20 to 40 cords per acre, and frequently much more. It has also been found that in this section of the country two cords of pulp wood are equivalent to three cords of the eastern pulp wood, this fact being due to the marked superiority of the western woods over the eastern with respect to size, lack of knots, and clearness. It is estimated that on each acre of logged-off land there are at least ten cords of pulp wood left to rot, due to the fact that there are relatively few pulp mills in this vicinity now, and also to the fact that there is no advantage to the manufacturer in securing such wood when the cheapness of other supplies of pulp wood is considered. When the total acreage of logged-off land is considered, together with the startling fact that for each acre of this land there are ten cords available at a cost involving little more than the cost of transportation, the immensity of the raw-material supply and the relative low cost may be comprehended.

In 1924 in the state of Washington there was a forest area of somewhere in the neighborhood of 12,000,000 acres containing 282,645,000,000 bd.ft. of merchantable timber divided up as follows:

| | |
|---|---|
| Privately owned | 173,350,000,000 bd.ft. |
| State owned | 23,027,000,000 bd.ft. |
| Federal owned | 86,268,481,000 bd.ft. |

The timber owners in the state number 12,000, and their average holdings run about 470 acres.

In 1924, from the different cruises in the different counties taken as a basis, Table 4 was compiled for the percentage of the total stand with respect to the different species. This percentage, of course, does not hold true for each county, but it does give a good idea of the relative stands with respect to each other. For instance, there is a strip some 30 miles wide along the ocean side of the Olympic peninsula which is practically all spruce. The hemlock is found mixed in with the Douglas fir, and usually grows at an altitude of less than 2500 ft. Between the 2500- and 3500-ft. contours is found the hemlock-silver fir type, and above this range is found the silver fir and western hemlock species. As the altitude increases the quantity and the quality of the timber decreases.

TABLE 4 SPECIES OF WOOD BY PERCENTAGE

| Scientific name | Common name | Percentage |
|---|---|---|
| Pseudotsuga Taxifolia | Douglas fir | 46 |
| Tsuga Heterophylla | Western hemlock | 21 |
| Thuga Plicata | Western red cedar | 12 |
| Pinus Ponderosa | Western yellow pine | 7 |
| Abies Nobilis | Silver-Noble fir | 5 |
| Pica Stichensis | Sitka spruce | 4 |
| Larix Occidentalis | Western larch | 2 |
| Pinus Monticola | Western white pine | 1 |
| All others not including cotton wood | | 2 |

In 1920 a survey was made by the government on the possibility of securing wood pulp in the northwest portion of the Northwest, and it was found that 635,000 cords of pulp wood could be obtained from the operations designed primarily for the lumber industry, neglecting the possibility of obtaining smaller and broken trees unfit for the lumber industry, but suitable for pulp manufacture. In considering the reforestation problem it is noticed that the possible growth in the Pacific Northwest is much faster than in the other sections of the country. While the average possible growth under intensive forestry for the spruce-fir type in the Northeast as a whole is estimated as 45 cu. ft. per acre per year, and in the Lake states as 35 cu. ft. per

acre per year, it is placed at 112 cu. ft. in the Northwest. In the Pacific states the minimum rotation of crops is placed at 30 years, as compared with 50 years for that of the Eastern states.

### Pulping Quality of Washington Timber

Species of trees vary over the United States and are quite definitely bounded within limited territories. In the state of Washington the species are limited, and this division is even more complete in that the Cascade Mountains make another quite definite boundary line for the different species. In the western part of the state the so-called Douglas fir predominates, with considerable stands of spruce, fir, and larch also existing.

A great deal has not been done up to the present time toward the development of the Douglas fir as a pulp wood. The saw-log value has been so high and the timber has been in such demand that the price has been prohibitive for the manufacture of pulp. As time goes on, however, it is being found that it is more and more profitable to operate the logging industry of the pulp woods in conjunction with that of the saw logs, and to go over the cut-off, saw-log lands for pulp wood. In the earlier stages of the logging operations in this country a great deal of the less desirable timber, which would be suitable for pulp wood, was left standing. In the determination of the desirability of wood for pulp it is found that there is a peculiar feature in some woods in the direction or density of the grain or fiber of the wood which adds much to the value of the tree possessing it. It is called the strength of fiber, and is the characteristic or quality of the wood which fits it for the manufacture of pulp from which paper, celluloid, card board, etc., are made. Poplars stand at the head of the list in the possession of this quality. Spruce is next, although the poplar and trembling aspen have slightly superior merits for the manufacture of pulp wood. Spruce is one of the predominating stands in Washington. Sitka spruce or Picea Stichensis is found along the entire Pacific Coast, the major growths extending inland for some 50 or more miles. Sitka spruce ranks very well with white spruce, the standard pulp wood of North America. Western hemlock outranks it at the present time in consumption on the Pacific Coast only because of the keen competition with the sawmills for the spruce logs, and the suitability of the less expensive hemlock for newsprint. At present one-half of the pulp wood consumed on the Pacific Coast is Western hemlock, which is largely used in the making of newsprint, but is also suitable for other paper uses.

### Study of Washington Timber Species

The yield of pulp from any given wood depends upon the specific gravity of the wood, the weight per cubic foot, and the pulping method employed. Below will be found an outline, which is taken from a bulletin of the Forest Products Laboratory at Madison, Wis., giving the pulping qualities of the different species found in the Northwest. In considering the pulping qualities and other data given for the different woods, attention is drawn to the following points:

1 The weights of wood given are for bone-dry material per solid cubic foot. This is obtained by multiplying the specific gravity of the oven-dried wood, based on the green volume, by 62.3 lb. (the weight of a cubic foot of water).

2 The fiber lengths as given are the average of all the available data taken from the Forest Service investigations and from other sources. Many of the measurements given are the results of averages of thousands of determinations; in other cases, from only a few determinations.

3 The yield figures represent the yield of bone-dry screened and unbleached pulp per hundred cubic feet of solid bone-dry wood. For the purposes of this article, it has been assumed that the ordinary cord of wood (rossed) piled 4 ft. by 4 ft. by 8 ft. is equivalent to 100 solid cu. ft. of wood. To convert the yields on bone-dry basis to air-dry pulp containing 10 per cent moisture, divide the yield by 0.9.

The yield data are based on results obtained from experimental runs made under very favorable conditions. The pulp logs on arrival at the laboratory are barked, sawed to convenient size, and any wood containing knots and decayed spots is rejected. The chips are carefully sorted and are far more uniform in size and moisture content than can be obtained in commercial practice, unless the mills operate under more favorable conditions than ordinarily exist. Further, each cook representing an individual experiment, it is possible to press, shred, sample and screen the pulp with fewer mechanical losses than is feasible in handling the pulp in commercial practice from the blow pit to the wet machine or to the finished paper.

4 The comparison of the character and uses of the various pulps that may be obtained from the different woods offers certain difficulties. It has, therefore, been decided to consider white spruce as the standard wood for pulping by the sulphite, sulphate, and mechanical processes, and to compare the pulp that might be obtained from any given wood by this process of pulping with the pulp obtained from white spruce. Aspen wood has likewise been adopted as the standard for reduction by the soda process, and soda pulps from other woods will be compared with it. Sulphate pulps made from deciduous woods bleach with greater ease and economy than the corresponding soda pulps.

*DOUGLAS FIR—Pseudotsuga Taxifolia*—Weight, 28 lb.; fiber, 4.4 mm.

- Sulphite pulp—Yield, 1200 lb.; character, hard to pulp, difficult to bleach, fair strength, poor color, pitchy; possible uses, few.
- Sulphate pulp—Yield, 1170 lb.; character, good grade of kraft pulp, but not as strong as white spruce; possible uses, similar to white spruce.
- Mechanical pulp—Because of high pitch content is probably unsuitable for this purpose.

*WESTERN YELLOW PINE—Pinus Ponderosa*—Weight, 24 lb.; fiber, 3.6 mm.

- Sulphite pulp—Yield, 1130 lb.; character, not difficult to pulp, difficult to bleach, shivey, very poor strength and color; possible uses, few.
- Sulphate pulp—Yield, 1100 lb.; character, fairly easily bleached, fine, high grade, very strong, and tough fiber; possible uses, same as white spruce.
- Mechanical pulp—Yield, 2060 lb.; character, fibers long, coarse, soft, creamy color, pitchy; possible uses, medium quality of groundwood.

*WESTERN HEMLOCK—Tsuga Heterophylla*—Weight, 23 lb.; fiber, 2.7 mm.

- Sulphite pulp—Yield, 1050 lb.; character, easily pulped, easily bleached, good strength, fair color; possible uses, same as white spruce.
- Sulphate pulp—Yield, 1100 lb.; character, good strong fiber; possible uses, similar to white spruce.
- Mechanical pulp—Yield, 2160 lb.; character, good strength and fiber, grayish color; possible uses, similar to white spruce.

*NOBLE FIR—Abies Nobilis*—Weight, 22 lb.; fiber, no data.

- Sulphite pulp—Yield, 1010 lb.; character, easily pulped and bleached, fair strength, excellent color; possible uses, substitute for white spruce.
- Sulphate pulp—Yield, 1080 lb.; character, good quality of strong pulp; possible uses, substitute for white spruce.
- Mechanical pulp—Yield, 1920 lb.; character, good color, long strong fiber; possible uses, same as white spruce.

*SILVER FIR—Abies Amabilis*—Weight, 22 lb.; fiber, no data.
Sulphite pulp—Yield, 1060 lb.; character, easily pulped and bleached, fair strength, good color; possible uses, same as white spruce.

*SITKA SPRUCE—Picea Sitchensis*—Weight, 24 lb.; fiber, 3.5 mm.
Sulphite pulp—Yield, 1080 lb.; character, easily pulped and bleached, excellent strength and color; possible uses, same as white spruce.
Sulphate pulp—Yield, 1150 lb.; same as white spruce.
Mechanical pulp—Yield, 2040 lb.; same as white spruce.

*WESTERN RED CEDAR—Thuja Plicata*—Weight, 19 lb.; fiber, 3.8 mm.
Sulphite pulp—Yield, 830 lb.; character, difficult to bleach, dark color but fair strength; possible uses, few.
Sulphate pulp—Yield, 830 lb.; character, rather difficult to bleach, fair strength; possible uses, same as white spruce.

*WESTERN LARCH—Larix Occidentalis*—Weight, 28 lb.; fiber, 2.6 mm.
Sulphite pulp—Yield, 1200 lb.; character, difficult to pulp and bleach, poor strength and color; possible uses, low grade wrappings.
Sulphate pulp—Yield, 1290 lb.; character, good quality of kraft fiber; possible uses, same as white spruce.
Mechanical pulp—Yield, 2100 lb.; character, brown color, short fiber, fair strength; possible uses, medium quality groundwood.

*LOWLAND WHITE FIR—Abies grandis*—Weight, 23 lb.; fiber, 3.2 mm.
Sulphite pulp—Yield, 980 lb.; character, easily pulped and bleached, fair strength, excellent color; possible uses, substitute for white spruce.
Sulphate pulp—Yield, 1140 lb.; character, good strong grade of kraft pulp; possible uses, same as white spruce.
Mechanical pulp—Yield, 1950 lb.; character, good strength, color and fiber; possible uses, same as white spruce.

*PORT ORFORD CEDAR—Chamaecyparis lawsoniana*—Weight, 26 lb.; fiber, 3.5 mm.
Sulphite pulp—Yield, 1150 lb.; character, fairly easily pulped, rather difficult to bleach, fair strength and color; possible uses, same as white spruce.

*ENGELMANN SPRUCE—Picea engelmanni*—Weight, 21 lb.; fiber, no data.
Sulphite pulp—Yield, 990 lb.; character, a little hard to pulp, excellent strength and color; possible uses, same as white spruce.
Sulphate pulp—Yield, 1000 lb.; character and possible uses, similar to white spruce.
Mechanical pulp—Yield, 2000 lb.; character, strong fiber of good color; possible uses, same as white spruce.

*LODGEPOLE PINE—Pinus murrayana*—Weight, 24 lb.; fiber, 2.3 mm.
Sulphite pulp—Yield, 1080 lb.; character, easily pulped, a little hard to bleach, excellent strength and color; possible uses, substitute for white spruce.
Sulphate pulp—Yield, 1120 lb.; character and uses, same as white spruce.
Mechanical pulp—Yield, 2140 lb.; character and uses, a little pitchy but otherwise same as white spruce.

*RED ALDER—Alnus Oregona*—Weight, 23 lb.; fiber, 1.2 mm.
Soda pulp—Yield, 1160 lb.; character, soft, harder to bleach than aspen; possible uses, same as aspen.
Mechanical pulp—probably same as aspen.

*PAPER BIRCH—Betula papyrifera*—Weight, 34 lb.; fiber, 1.2 mm.
Sulphite pulp—Yield, 1500 lb.; character, easily pulped, difficult to bleach, poor strength and color; possible uses, few.
Soda pulp—Yield, 1350 lb.; character, more difficult to reduce than aspen, soft, easily bleached; possible uses, similar to aspen.
Mechanical pulp—Yield, 3000 lb.; character, short fiber and poor strength, pinkish color; possible uses, as a filler with long-fibered stock.

*COTTONWOOD—Populus deltoides*—Weight, 23 lb.; fiber, 1.3 mm.
Sulphite pulp—Yield, 1035 lb.; character, easily pulped and bleached, very weak, excellent color; possible uses, same as aspen.
Soda pulp—Yield, 1030 lb.; character, soft and easily bleached.
Mechanical pulp—Yield, 2180 lb.; possible uses, as a filler when used with longer-fibered stocks; character, weak, short fibered, color good.

### Mill Waste as Raw Material

The use of logging and sawmill waste as a pulping material a few years ago was on the decline in the United States. This was accounted for by the fact that, in the past, the operation of a sawmill in any one place was more or less temporary. Also, the entrance of the pulping industry has hurried the departure of the sawmill from that locality, resulting in the loss of source of waste. There existed no association between the owners of the lumber-manufacturing concerns and those of the pulp mills which tended to raise the price of mill waste. When the time comes, however, that the pulp operations can be carried on in cooperation with sawmill operations, unsuitable logs and waste from the mills can be utilized cheaply for pulp purposes, and, as it has been found in Sweden, the price of manufacture will show a sharp decrease. About 8 per cent of the total wood now used in the industry is in the form of waste. At present this consists of hemlock and spruce slabs, and other large pieces, cut from peeled logs and freed from bark. There are at the present time several mills in the South which are operating exclusively on yellow-pine waste. On the West Coast there have been constructed during the past few years several large permanent sawmills, and quite a few of these have seen fit to add pulp mills, or have made provisions in their programs of expansion to include pulp mills in their scheme of operation.

### Power

The major considerations of the location of any industrial operation are: labor, market, power, and raw materials. In the case of the pulp industry the excessive freight rates on the pulp wood makes it necessary that the pulp mill be located in the vicinity of the raw materials. This fact brings up the question of suitable power at a practical cost. From a census taken of the different mills throughout the United States, and based on the ratings of the prime movers, it was found that about 85 per cent were electric motors. Of these, some 35 per cent were operated on purchased current and 65 per cent on current generated at the mills. Washington is one of the leading states in both the production of water power and in potential supply. Government geological data give the fact that one-sixth of the nation's supply is situated in the vicinity of Puget Sound. Very satisfactory rates may be had from the power companies now in operation; some mills now in operation are obtaining a rate of 4 mills per kw-hr. At practically all points of logical mill sites power may be manufactured in sufficient quantities for all mill needs. Due to the great number of saw mills, hog fuel may be obtained at a nominal rate, and the state possesses enough coal to last the nation some 125 years. The coal mined may not be of the highest quality, but it is comparatively cheap.

### Labor, Chemical Supply, Etc.

Washington has been the leading lumber-producing state since 1905, which assures the labor supply in so far as the logging end of the industry is concerned. There are at the present time pulp and paper mills in operation and little difficulty has been experienced in the lack of labor. The temperate climate also is tending to keep the labor turnover at a minimum.

In considering the materials needed for the chemical processes, it has been found that they are all easily available. Eastern Washington has great deposits of sodium sulphite, sulphur is found in sufficient quantities in Alaska, and native lime rock is found in most parts of the state.

### Water Supply

Water is another factor which plays an important part in the manufacture of paper. It is demanded in immense quantities, and many mills require 400,000 gal. of water per ton of product. It serves as a solvent and a carrier of chemicals in the digesters and cookers, it conveys the pulp through the various machines, and it is used in the boilers and heaters. The water supply is usually treated to remove suspended and organic matter, particularly living organisms. Much suspended matter causes irregularities in the texture and the appearance of the finer grades of paper, it clogs the screens of the different machines, and it also causes excess waste of the bleach and bisulphite liquors. Iron is very undesirable. Soft water is undesirable, due to the solubility of any form of calcium sulphate and the resulting waste that the mixture causes. Hard water deposits calcium carbonate on the screens used to separate the pulp from the liquors, and interferes in the sizing operation.

In a survey made by the Department of the Interior, a summary of the report states that an estimated 95 per cent of the river waters of the state are suitable for industrial purposes, and that they are unusually low in mineral content, having little suspended matter. Table 5 gives the chemical analysis of the principal rivers of the state.

TABLE 5 SURFACE WATERS OF WASHINGTON—MINERAL CONTENT IN PARTS PER MILLION

| River | Locality | Turbidity | Suspended matter | Coefficient of fineness | Silica ($SiO_2$) | Iron (Fe) | Calcium (Ca) | Magnesium (Mg) | Sodium and potassium (Na + K) | Carbonate radicle ($CO_3$) | Bicarbonate radicle ($HCO_3$) | Sulphate radicle ($SO_4$) | Nitrate radicle ($NO_3$) | Chlorine (Cl) | Total solids |

### Pulp-Making Processes

*The Preparation of Pulp Wood.* The processes employed in the manufacture of paper have undergone radical changes since the ancient days when paper making was strictly a hand process, but the fundamental principle involved has changed but little. To produce an even layer of closely intertwined fibrous material that will have strength and that will bear ink was the original concept of the makers of paper, which still holds true to this day. Of course the varied uses to which paper is put now, from the softest of tissues to the roughest of roofing paper, calls for a very much more complicated process involving a thorough understanding of the chemical and mechanical features that come into play.

This technical feature has resulted in much specialization, until now the details of the paper-making industry are thoroughly understood only by those actually engaged in the process, hence the layman must be contented with just a broad outlook on the whole situation. In the following paragraph a brief description of the preparation of pulp from wood by the four principal processes will be given.

The logs as they come to the mill are covered with bark, sand, and mud that must be removed before the wood can be used. The logs are first cut into either two-foot or four-foot bolts and then relieved of their bark by either of the following three methods:

1 In the smaller mills, and in mills handling a pulp wood whose bark can be readily removed, hand methods of removing the bark are used, but in the larger mills, machine methods are employed.

2 In the "barking drum" the four-foot bolts are introduced with water into a horizontal drum (as large as 45 ft. in length and 12 ft. in diameter), which is revolved at a slow speed by means of a gear drive. The drum is made open at the ends with strips of angle iron that project into the interior fastened longitudinally through its length. The rotation of the drum tumbles the wood over and over, and its bark is removed by the friction of the bolts against the rough surface of the drum and against each other. Eighty per cent of the pulp wood is stripped of its bark by this method, the pieces with bark intact being sent through the drum a second time. The cost involved in the process is low, the amount of wood wasted is small, and a large quantity can be handled per day. For this reason drum barking has been universally adopted for the preparation of newsprint wood.

3 In the "barking" or "rossing" process the pulp wood is pressed against a revolving disk about 4 ft. in diameter set with four or six radial blades projecting from its surface. As the disc revolves the wood is turned on its axis by a mechanism, and the bark, together with 10 to 20 per cent of the wood, is removed. The rossed wood is considered a better product than the drum-barked wood, and commands a price a few dollars per cord higher than the latter. The greater waste in the rossed wood is evident, however. Fig. 1 shows diagrammatically the manner in which materials are handled in the average plant up to the grinding process.

In some mills utilizing sawmill waste, two-foot spruce blocks free from bark, knots, and irregularities are used in great proportions. The weight of the pulp wood, in consideration of its transportation cost, is not as vital a factor in the Pacific Northwest as in some other sections of the country where the wood is hauled over some distance. However, where transport by rail at a published rate per 100 lb. is involved the weight of the wood becomes a serious factor, and explains why the barking and rossing plants are frequently located near the timber supply rather than at the mills. The wood is handled in mechanical

splitters at this point to convert it into handier sizes for the coming processes.

*The Manufacture of Mechanical Pulp.* The importance of mechanical pulp in the American paper industry, especially in supplying the demands for cheap newsprint, should not be overlooked. The United States Department of Agriculture issued figures for 1922 showing that "Mechanical pulp made up slightly over 2,580,000 tons of American pulp requirements in 1922, or 44 per cent, and constituted the largest pulp grade. Since, however, the yield per cord by the mechanical process is relatively high in terms of pulp wood, the 1922 requirements for mechanical

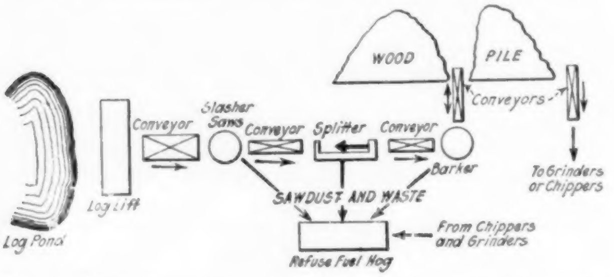

Fig. 1 Flow Diagram from Log Pond to Grinding Room

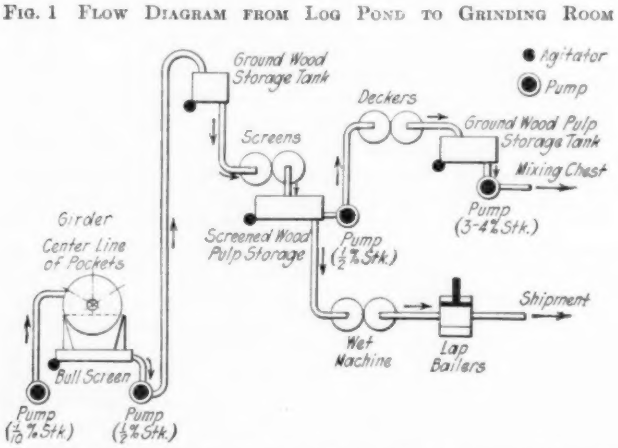

Fig. 2 Flow Diagram of the Mechanical Pulping Process

pulp were slightly less than 2,600,000 cords or only 20 per cent of the total."

The wood species used in the Pacific-Coast region for the mechanical process are largely spruce, cottonwood, and hemlock, with some white fir. Many mills are in operation also whose main source of pulp wood is the wastewood gathered from the lumber mills.

Mechanical pulp alone is very seldom used in the manufacture of paper, but it does form a large percentage of newsprint, paper boards, wrapping paper, etc. The percentage to be added varies all the way from 15 to 80 per cent, depending upon the quality, strength, and the appearance of the paper desired.

In this process the fibrous constituents of the wood are torn apart by mechanical abrasion. The grindstone for the two-foot blocks has a face 27 in. wide and a diameter of 54 in., and is mounted horizontally in a heavy cast-iron box. There are three pockets over its circumference into which the blocks can be placed under a five-ton hydraulic pressure, giving a unit pressure about 40 to 50 lb. per sq. in. In the grinding room of the 25-ton mill at Edmonds, Wash., a 1250-hp., 60-cycle, 3-phase synchronous motor is direct connected to two grinder units, each with three pockets. The stone is rotated at 257 r.p.m. The capacity of the 27-in., 3-pocket grinder is about 8 tons of pulp per 24 hours, on an air-dry basis. Later tendencies have been toward the utilization of 4-ft. bolts on a 54-in. faced grindstone, and with better efficiency. The latest developments, however, have been toward the installation of 4-pocket grinders, which feed the wood in a steady stream from a magazine without losses in time or production.

A stream of water is added continuously to the abrasive surface of the stone. A minimum quantity of water gives a product termed "hot ground" pulp, which is a coarse-fibered pulp resulting from the tearing apart of the wood. The production of the hot-ground pulp is greater than that from the cold-ground pulp, which is produced by adding an excess amount of water to the stone, but the fibers are not as fine or uniform in grade.

The pulp is carried by the flowing water into a chamber below, where it passes through a series of screens. The mesh varies in size from 0.4 in. for the initial screens to 0.012 in. for the finer screens. The fine pulp is carried by the excess water to the wet machine, where it is formed into thick sheets by the removal of

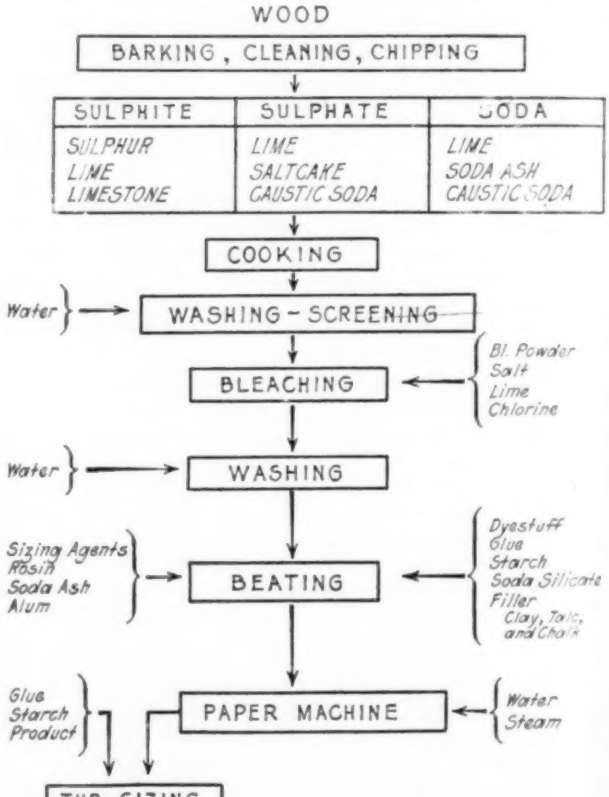

Fig. 3 Diagrammatic Illustration of the Chemical Process of Paper Making

water. Fig. 2 shows in diagram the flow of materials in this process.

The wet machine consists of a partially submerged screen cylinder rotating in a large vat. As the drum rotates the water passes through to the inside of the drum, leaving a thin layer of pulp on the outside of the wire cloth. The layer of pulp is removed from the top of the drum by an endless felt, which is held in close contact with it by means of the pressure from the couch roll, causing the web of the pulp to adhere to the felt. The pulp is wound up on a large wooden cylinder until a good sized sheet is formed, when it is cut across and removed.

The water content at this stage is about 70 per cent, but if shipments are to be made in the form of bales the sheet pulp

is placed with alternate pieces of sacking into a hydraulic press where a fifty per cent air-dry pulp is obtained. (Air-dry pulp is pulp containing 10 per cent moisture, an amount that absolutely air-dry pulp will absorb from the atmosphere.)

As may be expected, the resulting pulp contains practically all the constituents of the original wood, has little strength, and is not of permanent character. Simplicity, however, serves to make the process much cheaper than the chemical processes, and hence it is used whenever the quality of the paper does not demand the finest of pulp stock.

*The Soda Chemical Process.* The diagrammatic sketch of Fig. 3, prepared by A. Krimmel of the Hammermill Paper Company, illustrates the three common chemical processes; namely, soda, sulphite, and sulphate processes. Here are illustrated the main constituents and the processes involved in the manufacture of chemical pulp. In the mechanical process the pulp fibers obtained are identical to the actual composition of the wood itself. In the chemical process, however, the wood is partially dissolved by chemicals, and a fiber of nearly pure cellulose is obtained. All three processes are found on the Pacific Coast, and a high-grade product is being turned out by the mills. In the soda chemical-process mills the prepared bolts of wood from the barking process are carried by conveyors to the chippers, steel or cast iron disks 7 ft. in diameter, set with two or three radial knives on the surface and operating at 200 r.p.m., where they are reduced to chips about $^1/_2$ in. thick. These chips

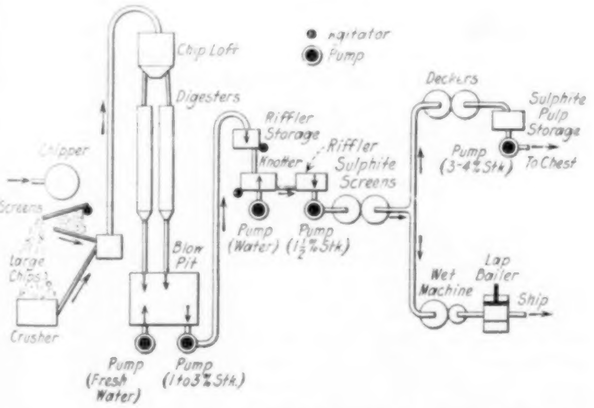

FIG. 4 FLOW DIAGRAM OF THE CHEMICAL PULPING PROCESS

are next broken into smaller pieces by crushers or disintegrators, following which they pass through screens. The screened chips are then carried by conveyor belts to bins directly above and opening into the digesters. The chemical used is sodium hydroxide. High-pressure steam is admitted to the digesters to aid the action of the chemicals. Fig. 4 illustrates the flow of materials through a plant employing the chemical process.

The stationary digester in which the cooking is accomplished is cylindrical in form, 28 ft. high by 7 ft. in diameter, and made of $^1/_2$-in. plates, conically shaped at both top and bottom. The ordinary charge of four cords requires approximately 3500 gal. of liquid, and requires about eight hours for complete digestion. The pulp sludge is then blown into the "blow pit," a large covered tank with a false bottom set about a foot above the inclined permanent bottom. The pulp settles to the false bottom, while the liquid drains through and is pumped to the recovery tank.

A thorough washing is then required to remove the chemicals from the pulp before it is passed to the bleachers. The bleaching operation is performed in a conical basin about 10 ft. high by 5 ft. in diameter, containing an inner cone, at the bottom of which is a mechanically operated screw device which keeps the pulp in a continuous circulation up the inner cone and down the sides while a bleaching solution of CaClOCl which forms HClO in solution.

*The Sulphate Process.* In this process chips about 1 in. to $1^1/_4$ in. in size, together with the liquid digesting solution, are fed into stationary digesters similar to those described in the soda process. The solution used contains sulphur in the form of a sulphide and is alkaline in character. Superheated steam at 440 deg. fahr. and 125 lb. pressure is used in connection with the solution. A thorough washing to remove chemicals follows the completion of cooking. The sulphate process has a distinct advantage in the Pacific Northwest where the resinous woods are found. The sulphate mills being equipped at the present time are utilizing hemlock and fir slab waste from the sawmills, which indicates the importance of this process in the economical utilization of our forest resources. The product classified as "Kraft" pulp is of great strength and is demanded by manufacturers of wrapping paper.

*The Sulphite Process.* The dissociation chemicals used in this

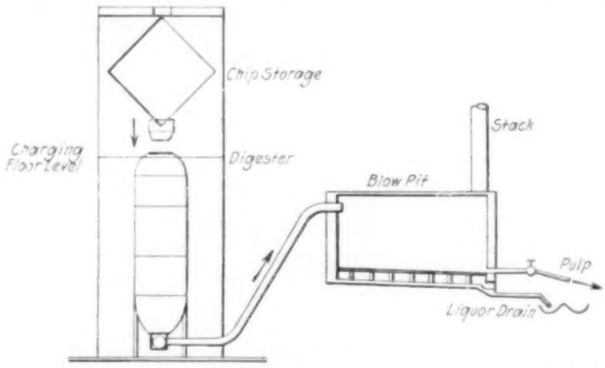

FIG. 5 DIAGRAM OF DIGESTER AND BLOW PIT IN A SULPHITE MILL

process are composed of sulphurous acid and the bisulphites of lime and magnesia. The woods are mainly spruce and hemlock with yields running close to 1000 lb. per cord. The cooking operations are somewhat similar to those described in the soda process, and the washing process takes place after the liquid has been drained off through the screen bottom of the blow pit, shown in Fig. 5, which also shows the digesters used in this process. About three hours is consumed in washing, after which a fine fibrous pulp results. In the soda and sulphate processes previously described elaborate chemical-recovery methods are employed, but in the case of the sulphite process no attempt is made to reclaim the chemicals. However, chemists are investigating the possibility of further utilization. Owing to the fact that the non-fibrous portion of the wood dissolved in cooking represents about one-half of the original wood, about 50 per cent of the raw material for the sulphite process is wasted. The process is relatively expensive, since only about 30 per cent of the original air-dry wood is converted into pulp. The product, however, is of excellent quality and is frequently mixed with the cheaper mechanical pulp in order to give the latter sufficient strength for the manufacture of newsprint.

### PROCESS OF PAPER MAKING

The paper-making process as carried on in the Pacific-Northwest region is practically identical with that in any other section of the country, except in the variations of the refining and sizing operations, and hence will not require treatment here.

Before admitting the pulp to the machine the fiber is made resistant to the ink by the addition of some form of animal or vegetable size or glue, which must be applied to the paper either as

a coating on the sheet or mixed with the pulp in the beating machines. The latter process, known as engine sizing, consists of filling up the interstices of the fiber with a chemical precipitate of finely divided rosin, which when dried on the paper machine makes the paper resistant to moisture. Cheap loading material, such as china clay, kaolin, or calcium sulphate, are added to a moderate extent of from 10 to 15 per cent to close up the pores of the paper. This makes the paper softer and gives the surface a smooth glaze which is especially good for writing and printing. Pigments and colors also are added at this point as required. A process of refinement known as the Jordan process, and consisting of a constant agitation of the pulp to prevent settling of

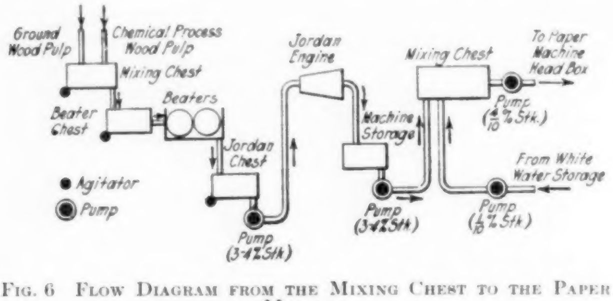

Fig. 6 Flow Diagram from the Mixing Chest to the Paper Machine

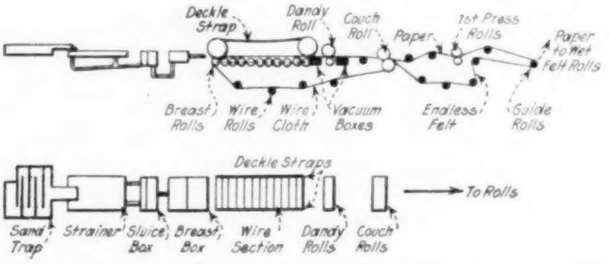

Fig. 7 Diagram of the Wet End of the Fourdrinier Paper Machine

the fibers, precedes admission to the machine storage and mixing chest.

Fig. 6 shows in diagram the flow of materials from the mixing chest to the paper machine. Fig. 7 shows diagrammatically the wet end of the Fourdrinier paper machine and follows the several operations through to the final roll of paper.

## Consumption of Wood Pulp

*Consumption by Process.* There have been described on the preceding pages the four principal methods of manufacture of wood pulp. These can be divided into two principal groups with respect to consumption, the mechanical and the chemical, the latter again being divided into three grades: the soda, the sulphate, and the sulphite. The mechanical, or groundwood, pulp constitutes about 80 per cent of the ingredients of newsprint, of which millions of tons are manufactured annually. It is also used to some extent in the manufacture of other grades of paper and board. Bleached soda pulp is largely an American product and is used most commonly in a variety of both colored and white papers, such as book paper, etc. Sulphite pulp, both bleached and unbleached, is used most extensively throughout the world, due to its variety of grades. When bleached it is the cleanest and the whitest of all pulps, and when mixed with rags gives a very high grade of paper and board. Very good paper is also made from the pure, bleached sulphite pulp, or from a mixture of this and other high grades of wood pulp or reclaimed stock, but such paper is usually inferior in strength and durability to that made from the addition of the first raw materials for paper making—rag stock. Bleached sulphate is used in the manufacture of higher grades of paper.

In the year 1924 the consumption of wood pulp was distributed as shown in Table 6 in the four different processes:

TABLE 6 CONSUMPTION OF WOOD PULP IN 1924

| Process | Cords | Percentage |
|---|---|---|
| Mechanical | 1,643,955 | 28.5 |
| Sulphate | 626,022 | 11.0 |
| Sulphite | 2,691,492 | 46.5 |
| Soda | 806,613 | 14.0 |
| Total | 5,768,082 | 100.0 |

The United States far outranks the other countries of the world in the use of paper, as is shown in Table 7, covering annual consumption in the year 1920.

TABLE 7 PAPER CONSUMPTION OF UNITED STATES IN 1920 AS COMPARED WITH OTHER COUNTRIES

| Country | Pounds per Capita |
|---|---|
| United States | 148 |
| Great Britain | 75 |
| Germany | 45 |
| Scandinavia | 33 |
| Japan | 11 |
| Russia | 5 |

In 1922 there was used in the United States newsprint paper alone at the rate of 45 lb. per capita. Some 74 per cent of the paper used was made of wood, and of this 74 per cent some 56 per cent was purchased. From the year 1916 there has been a decided advance in the importing of pulp wood which is not altogether due to the inability to compete with the foreign countries in the manufacture, but to the decided increase in the demand. In 1922 there was a total of 1,259,000 short tons of wood pulp imported into the United States, largely from Sweden and Canada. This total was divided up into 215,000 tons of groundwood, 714,512 tons of sulphite, and 328,000 tons of sulphate. In the same year the United States only produced some 3,521,600 tons, which means that 26 per cent of the pulp wood available for consumption was imported.

In 1926 the United States imported more than 1,700,000 tons of pulp, 300,000 tons being mechanical and 1,400,000 tons sulphite and sulphate, an increase of 441,000 tons per year in the past four years. These figures are exclusive of the wood imported and manufactured into pulp in this country, which amounted to some 1,500,000 cords. In this same year it is estimated that not over 2,000,000 lb. of paper were made from wood grown in America. Also, 4,300,000 tons of paper were made from reclaimed stock and home-grown wood, as compared to 3,521,000 tons in 1922. The pulp consumption has been increasing from 5 to 7 per cent annually, and of this total quantity of pulp used approximately 22 per cent is from wood grown in the United States.

In Fig. 8 it may be seen that the consumption of pulp has steadily increased since 1922, which was an abnormally low year. It may also be seen that the imports have increased with the consumption, which shows that the home production has not kept pace with the consumption.

*Consumption by Species.* From the statistics compiled for 1924 it is found that the wood consumption by species was as shown in Table 8.

TABLE 8 WOOD CONSUMPTION IN 1924, BY SPECIES

| | Per cent of total consumption |
|---|---|
| Spruce—Domestic | 36.1 |
| Imported | 15.4 |
| Hemlock | 16.7 |
| Yellow Pine | 7.4 |
| Poplar—Domestic | 3.8 |
| Imported | 2.7 |
| Balsam Fir | 5.4 |
| White Fir | 1.6 |
| Larch | 1.3 |

None of the other species formed more than 5 per cent of total.

### Production of Wood Pulp

*In the United States.* Every portion of the United States is engaged in the production of wood pulp to a greater or less degree, the center of production in the past having been in the New England States. In recent years, however, the pulp industry has spread to an unbelievable extent, and has not, as have most industries, moved from one locality en masse to another, but has branched out all over the United States. Table 9 gives a very good idea of the general distribution of the industry, having been compiled for the year of 1924. Since that time the expansion has been on an even greater scale, the principal tendency being towards the Southern States, and in the course of the past year towards the Pacific Coast States.

TABLE 9 PRODUCTION OF WOOD PULP BY QUANTITY AND VALUE, BY STATES

| State | Quantity, Tons of 2000 lb. | Value in dollars Total | Average per ton |
|---|---|---|---|
| United States | 3,723,266 | 186,724,129 | 50.15 |
| Maine | 895,451 | 41,823,676 | 46.71 |
| New York | 755,156 | 33,540,521 | 44.42 |
| Wisconsin | 609,081 | 30,475,682 | 50.04 |
| Pennsylvania | 216,862 | 16,315,962 | 75.24 |
| Washington | 159,539 | 5,265,969 | 33.01 |
| New Hampshire | 151,863 | 11,296,230 | 74.38 |
| Michigan | 145,565 | 8,080,260 | 55.51 |
| Minnesota | 141,165 | 6,236,781 | 44.18 |
| Virginia | 136,105 | 8,620,315 | 63.34 |
| Louisiana | 52,872 | 2,180,553 | 41.24 |
| Vermont | 45,587 | 1,672,485 | 36.39 |

Throughout the United States there is a total of not less than 1680 mills engaged in the pulp and paper industry; of these, 840 are paper mills, 315 are pulp mills, and 525 are pulp-less paper mills.

*In Washington.* At the present time it is difficult to approximate the production of wood pulp in the state of Washington for any definite period of time, as there are announcements every day of the construction of new mills or the expansion of older mills. At the present time a great many of the established lumber companies are investigating the industry with an idea of operating the pulp industry in conjunction with the lumber mills. This is particularly feasible at the present time, due to the fact that the mills have as a rule cut the timber on the lower levels and have moved back to where there is a greater percentage of hemlock in their timber stands. Then, too, the constant inquiries by Eastern capitalists regarding the possibility of locating sites, as well as the floating of new bond or stock issues for new mills, brings the matter of pulp production in the state within the realms of pure guesswork.

### Importation of Wood Pulp

As is shown in Fig. 8 the imports comprise a large part of the total consumption in the United States. This fact is particularly true of the state of Washington, and it is found that 37.7 per cent of the sulphite pulp, which formed 29.2 per cent of the total consumption, was imported; 15.2 per cent of the mechanical, which formed 24.7 per cent of the total, and 44 per cent of the sulphate, which formed 9.6 per cent of the total, also was imported; the balance of the consumption being taken care of within the state. There was practically no exportation of the different pulps. These figures hold true for pulp only, as it has been found that the imports of paper were not so marked. Only 47 per cent of the total consumption of newsprint, which formed 28.8 per cent of the total consumption, was imported, and as in the case of pulp there were practically no exports.

### Exportation of Wood Pulp

There exists a great possibility in the future development of the export trade in Washington. By no means is the education of the Oriental countries to the use of paper a minor one. The paper mills of Japan alone consumed 769,301,726 lb. for nine months of the year 1926, the pulp for all of this being imported, since the Japanese Government has forbidden the cutting of pulp wood for some time to come. The new Occidental Pulp Mills at Edmonds, Wash., have contracted to furnish a Japanese paper mill with 400 tons of pulp per month during the year of 1927, which indicates the beginning of a coming export-trade prospect. There is no locality with a better situation than Washington for supplying this market.

The Department of Commerce states that more than $3,000,000 worth of paper is exported annually to the territories. Alaska consumed paper to the value of $250,000 and Hawaii consumed

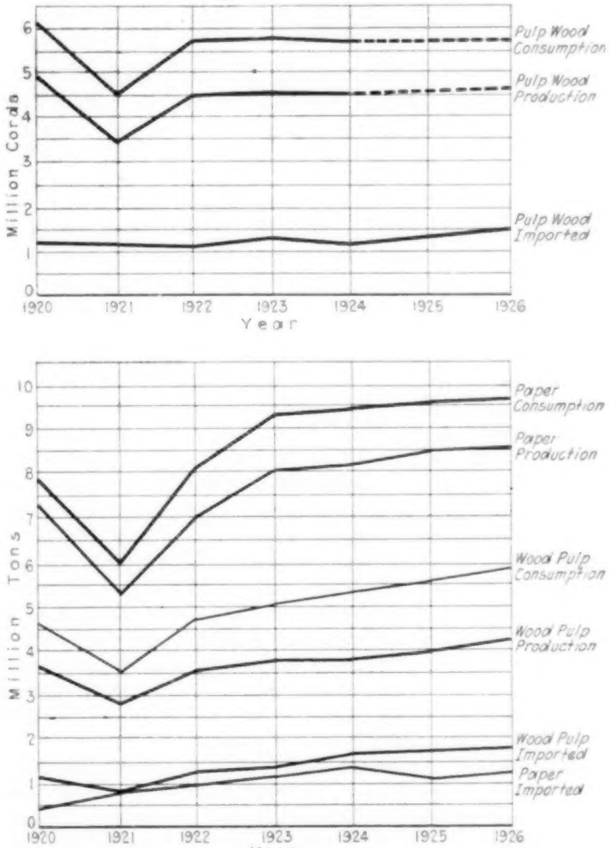

FIG. 8 CONSUMPTION, PRODUCTION, AND IMPORTS OF PAPER, WOOD PULP, AND PULP WOOD IN THE UNITED STATES

from $1,000,000 to $1,500,000 worth, which is more than 50 per cent of the exports to the territories.

As an indication of the possible markets of pulp from this section of the country, it is interesting to note that one steamship company states that there is in excess of 1000 tons of pulp per month loaded for Havana.

The paper markets of the lower half of the Western Hemisphere have been dominated by the German mills, but in view of the distance between Germany and these markets, it seems logical to believe that as soon as production has reached the stage where it can take care of the home market, there are wonderful possibilities in competing with the Germans for these markets.

### The Location and Production of Mills

With one exception the paper mills of Washington are located west of the Cascade Range; this single exception being the mill at Spokane, which finds a market for its product in Texas and Oklahoma. The balance of the mills are located along the coast,

and an incomplete list of the present mills is given in Table 10, together with their location and approximate rated capacity.

TABLE 10 PAPER MILLS IN WASHINGTON—CAPACITY BY SPECIES—TONS

| Location and name | Mech. | Sulphite | Soda | Sulphate |
|---|---|---|---|---|
| Camas—Crown Willamette Paper Co. | 90 | 155 | .. | 100 |
| Lowell—Everett Pulp & Paper Co. | .. | .. | 60 | .. |
| Port Angeles—Wash. Pulp & Paper Co. | 220 | 75 | .. | .. |
| Port Angeles—Paraffine Co. | 30 | 30 | .. | .. |
| Sumner—Paraffine Co. | 35 | .. | .. | .. |
| W. Tacoma—Cascade Paper Co. | 50 | .. | .. | .. |
| Spokane—Inland Empire Co. | 75 | 30 | .. | .. |
| Edmonds—Occidental Pulp Mill | 40 | .. | .. | .. |
| Vancouver—Columbia River P. Co. | | | | |
| Bellingham—San Juan Pulp Mfg. Co. | 45 | .. | .. | .. |
| Bellingham—Pacific Coast Paper Mill | | .. | .. | .. |
| Anacortes—Anacortes Box & Lbr. Co. | 50 | .. | .. | .. |
| Tumwater—Tumwater Paper Mills | 20 | 50 | .. | .. |

Much difficulty was met in securing accurate information as to the mills in operation, but the table contains practically all those of importance at the time of writing.

### Transportation Facilities

*Water Rates.* The Pacific Northwest is particularly fortunate in its transportation facilities. Puget Sound makes an indentation in the coast line, with harbors equal to any in the world. It is accessible at nearly all points to any of the 119 steamship lines that have Seattle as their port of call. The shore line is so characterized that the mills may be built directly on the water front and the products loaded directly on the boats without the costly loading and reloading of short railroad hauls. In the southern part of the state the Columbia River is navigable far into the timbered region, permitting loading direct from the mills, as is the case on Puget Sound. Due to the competition with the railroads the intercoastal service is of the best, and the efforts of the steamship companies operating to the Orient to retain their position in commerce makes this service also very good. Competition between trucking lines, the railroads, and the steamship lines, make the Pacific Coast service all that could be desired. To the East Coast, north of Charlottesville, N. C., for a minimum of 24,000 lb. when compressed to 51 cu. ft. per short ton, there is a rate of 35 cents per hundred pounds. To the Orient, Yokohama, Manila, and Hongkong there exists a rate of six dollars per weight ton, and to Shanghai a rate of six dollars and fifty cents per weight ton.

*Freight Rates.* As is the case with the various steamship lines, the Pacific Northwest receives the benefits resulting from the keen competition among the railroads. There are at present four trans-continental railroads serving this district which have branch lines, or which connect to privately owned lines, covering practically the entire state. This is especially true in the timbered districts, due to the fact that the different lumber companies have constructed railroads into the timber districts, where there was not one already, to transport their logs.

### Cost of Production

No definite figures can be compiled as to the cost of production for the Pacific Northwest with respect to either the pulp or the paper manufacture, as the conditions vary almost from day to day and from locality to locality. Mills are at present in operation ranging in capital invested from $150,000 for a two-grinder pulp mill, to $5,000,000, the latter figure being the estimated cost for a mill now being planned for construction at Bellingham. In comparison with Eastern conditions, it is found that the cost of pulp wood at the mill is less than one-half per cord, and for the immediate future at least, according to some authorities, this price will decrease and not increase. Wage scales are about on a par with the East, although they may be a little higher here. The cost of construction of the plants is decidedly cheaper on the Pacific Coast.

The cost of chemicals is but slightly higher than in the East, and as time goes on and the resources of the West become more developed these prices will be reduced.

Following is given the prevailing market prices for the various pulp products for January, 1927:

| | |
|---|---|
| Foreign— | |
| Ground wood per moist ton | $0.36 to $0.38 |
| Ground wood per dry ton | 0.38 to 0.42 |
| Domestic— | |
| Ground wood per moist ton | 0.30 to 0.33 |
| Imported— | |
| Bleached sulphite | 3.75 to 4.50 |
| Unbleached sulphite | 3.00 to 3.15 |
| Bleached sulphate | 3.75 to 4.00 |
| Prime Kraft pulp | 3.05 to 3.10 |
| Domestic— | |
| Bleached sulphite | 3.65 to 4.75 |
| Unbleached sulphite | 3.25 to 3.75 |
| Prime Kraft pulp | 3.00 to 3.50 |

### General Summary

Of all the great national industries the paper industry receives probably least advertising despite the fact that its products are essential to the industrial life of the nation, and to the moral and educational development of its people. Over 10,000,000 pounds of paper and paper goods were manufactured in the United States during 1926. Even in the state of Washington, according to the latest Federal census, where the pulp and paper industry is in its infancy, it is among the ten leading industries. At present the recognized center of the industry is in the East. There is a great business transition going on at present throughout the United States due to the shifting of the tide of population, to the uncovering of new sources of raw materials, to the location of new routes, and to better methods of transportation. This is particularly true of the pulp industry. According to authorities, reforestation has not been highly successful in the Eastern States, and it is asserted that the Eastern mills have no assurance of an adequate supply of wood for more than five or ten years. The logical solution is to go where the raw materials are found in abundance. Due to the immensity of the industry it cannot be located in any one locality, as is the case with other industries, but there will be a recognized center of trade, and from all appearances that center will be in the Northwest. This is only logical in view of the enormous stands of virgin timber, the decided superiority over other sections in the success of reforestation, and innumerable other factors which govern the development of the industry.

Not alone in the success of reforestation does Nature seem to favor the Northwest. She has provided the necessary raw materials in sufficient quantities, and has supplied an abundant supply of pure water and hydroelectric power to suffice for the entire pulp and paper industry. As the years go by and the methods of transportation advance it will be found that the Northwest is not far removed from the balance of the world, as it was considered a few years ago. It has ideal shipping facilities and some of the best harbors in the world. The Northwest has an established lumber industry which makes the logging problem a secondary one as far as methods, labor supply, etc., are concerned. There exists an ideal climate with small variations in temperature throughout the year, making year-around operations possible in practically all sections of the country, which results not only in the curtailment of loss due to idle machinery, but also those resulting from frequent labor turnover. The pulp and paper industry capitalists have not lost sight of these facts, and at the present time established concerns, as

well as newer ones, are either constructing plants or are investigating sites for possible location.

Manufacturers of mill equipment have been established; mill engineers, operating consultants, etc., have migrated and established offices in this section of the country, as have paper brokers and consumers; all of which shows that in the minds of a great many experts the Northwest is the coming field in the pulp and paper industry.

The Federal Government has adopted a very liberal policy toward the pulp industry with respect to its timber lands, as has the state government. The state has also taken a definite step towards sponsoring a laboratory, similar to the government laboratory at Madison, Wis., which is to be located at the University of Washington with the idea in view of solving the different problems that arise in the pulping of the western woods.

The developments are going on by leaps and bounds; what has been written today on the industry is no longer true for tomorrow; but that does not deter the authors from making this very rough survey of the entire field as it now stands, in the hopes that it may be a condensed summary of the radical changes taking place and a guide to the industry of tomorrow.

# Change in Moisture Content of Lumber During Rail Shipment

## Results of Some Tests Made on Shipments of Douglas Fir Lumber Shipped by Rail During The Winter Season From the West Coast to Chicago

By G. E. FRENCH,[1] MADISON, WIS.

ENGINEERS are interested in the degree of seasoning at which standard sizes of lumber apply, and frequently also in the possibility of obtaining lumber of some specific moisture content that fits it for a special use without the risk of changes in dimension due to shrinkage and swelling. It is therefore important to know to what extent the moisture content of lumber changes during the long rail hauls that are now a common necessity of lumber marketing.

This paper presents the results of an investigation made to determine whether or not lumber placed aboard cars at the sawmill at a low moisture content will change in moisture content during transit to such a degree as to defeat the purpose of careful seasoning for general or specific uses.

As a preliminary step in the study, representatives of the Forest Products Laboratory and of the Forest Service district products office, Missoula, Mont., early in 1926, determined the change in moisture content of six carloads of lumber shipped from Idaho to the vicinity of Chicago. The late winter and spring season was selected as the time for the tests because this is the period of highest humidity of the year. In the six cars tested containing largely inch-thick flat stock of white fir, western yellow pine, and western white pine, the moisture change of material while in transit was slight except for some material with an average moisture content of 30 per cent that lost about 5 per cent.

In view of the small changes which these shipments showed, the Forest Products Laboratory decided in 1927 to determine not only the change in average moisture content for carloads of lumber but to show in what portion of the load local changes, if any, were taking place. The cooperating company, whose plant is located in western Oregon, was shipping clear grades of Douglas fir kiln-dried to an average of 8 per cent moisture content and common grades of Douglas fir kiln-dried to approximately 20 per cent. Five cars of flat clears were tested, one car of clear quarter-round and crown molding, and one car of common shiplap. Eighteen sample boards were placed in the same relative position in each car. They were protected from any extra-moist boards in the vicinity by being placed between check boards of approximately the same moisture content as the sample. Each sample board was sampled for moisture content and weighed to the nearest hundredth of a pound at the time it was placed in the car. At destination (Chicago) the sample boards were again weighed and moisture-content tests were made. As a check upon these two methods of determining the change in moisture content the total weight of each shipment was determined at the point of origin and destination by weighing the car loaded and empty. The results obtained by all three methods, namely, (1) change in weight of sample boards, (2) change in weight of total shipment, and (3) change determined by moisture-content determinations of the samples at origin

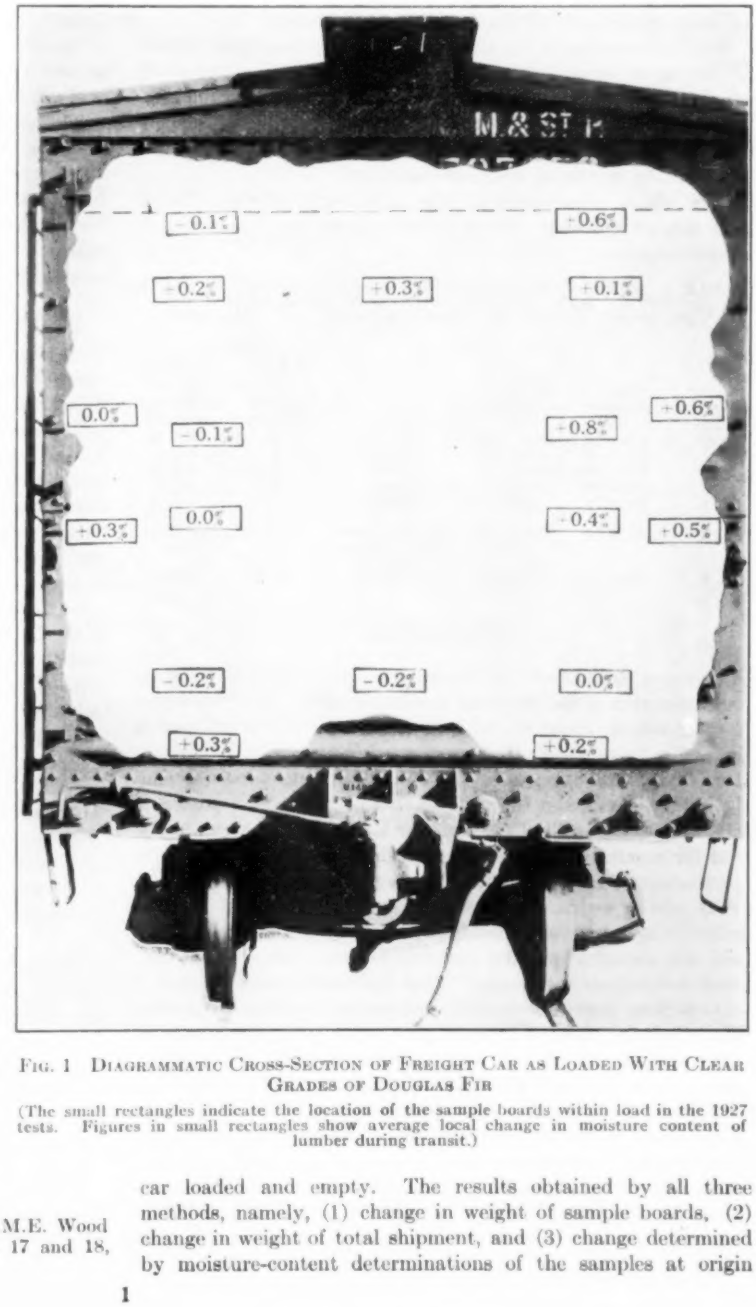

Fig. 1 Diagrammatic Cross-Section of Freight Car as Loaded With Clear Grades of Douglas Fir

(The small rectangles indicate the location of the sample boards within load in the 1927 tests. Figures in small rectangles show average local change in moisture content of lumber during transit.)

and destination, were so similar that only those changes shown by the sample-board weights need be considered here.

The data obtained are shown in Table 1 and illustrated graphically in the diagrammatic cross-section of the freight car in Fig. 1. For the five cars of flat clear Douglas fir the average change in moisture content was a 0.2 per cent increase (based on the oven-dry weight of the samples); for the more loosely loaded molding, 0.8 per cent increase; and for the common lumber, a loss of 0.4 per cent. The changes were so small as to fall well within the possible error of moisture determinations. The samples distributed throughout the loads gave no definite indications of local changes. As all of these shipments were made from the West Coast two-thirds of the way across the continent, with only the ordinary precautions used in loading box cars during the wettest period of the year, it is quite reasonable to conclude that during the usual haul in good box cars no appreciable change in moisture content of lumber need be expected.

This information is significant. It means that stock placed in the car in satisfactory condition as to moisture content will reach the unloading point in practically the same condition. If, on the other hand, it is received in bad condition by the consignee, the fault, unless the car is in a poor state of repair, must be with the seasoning methods employed.

The virtual elimination of this "unknown" between shipper and consignee brings the moisture-content problem one step nearer solution.

TABLE 1 CHANGE IN MOISTURE CONTENT OF DOUGLAS FIR SHIPPED BY RAIL DURING THE WINTER SEASON FROM THE WEST COAST TO THE VICINITY OF CHICAGO

| Carload shipment No. | Date shipped, 1927 | Date reached consignee, 1927 | Grade | Average moisture content when loaded, per cent | Change in moisture content in transit, per cent |
|---|---|---|---|---|---|
| 1 | Jan. 25 | Feb. 10 | Clears | 8 | +0.2 |
| 2 | Feb. 4 | Feb. 28 | Clears | 8 | +0.3 |
| 3 | Feb. 10 | Mar. 4 | Clears | 10 | +0.3 |
| 4 | Mar. 18 | April 5 | Clears | 9 | −0.1 |
| 5 | Mar. 25 | April 16 | Clears | 7 | +0.3 |
| Av. | | | | 8 | +0.20 |
| 6 | May 5 | May 25 | Quarter-round and crown molding | 8 | +0.8 |
| 7 | May 6 | May 24 | Common | 21.0 | —0.4 |

## Discussion

ARTHUR KOEHLER.[2] At present the old method of moisture determination is the one most commonly used. In this method a cross-section about $^3/_4$ in. wide is cut out of a board, and is immediately weighed. It is next dried in an oven at a temperature of 212 deg. fahr. until the sample no longer loses weight. It is then considered to be "oven-dried." It is well known to chemists that not all of the moisture is removed by this process, but for practical purposes it is considered absolutely dry. The percentage of moisture is then computed from the two weights. With pitchy woods, like pine and Douglas fir, there is a loss in oils that are also evaporated from the wood; ordinarily, however, this is a negligible quantity and does not affect the moisture content determination seriously. This is a cumbersome method of determining moisture content, and we are working to produce some simpler method. Some promising pieces of apparatus have been developed, but they are not yet ready for commercial use. There is a definite relation between moisture content in wood and the humidity of the atmosphere when at equilibrium, irrespective of the species, but a piece of light wood like poplar will change in moisture content more rapidly than a piece of heavy wood like white oak. Therefore, over a limited period of time, such as is required for shipment, it might be possible for one kind of wood to pick up more moisture than another kind. Moreover, sapwood and heartwood are not influenced equally. Sapwood will take on and give off moisture more rapidly. The size of the piece also has a great deal of influence. A large timber has less surface expanse for its volume than a small piece, therefore less change in moisture content is to be expected, but Table 1 of the paper shows that even a carload of molding, which consists of small dimensions, did not suffer serious change in moisture content during transit.

[2] Forest Products Laboratory, Madison, Wis.

THOMAS D. PERRY.[3] The results of the tests are very interesting, but two very essential points are missed. So far as I know, most furniture men who import lumber in freight cars either want it what they call "well air-dried," or kiln-dried, which means a moisture content of 4 or 5 per cent. If the lumber is air-dried and contains about 15 per cent of moisture, I do not believe lumber in this condition will give off much moisture in transit. The author's test shows that lumber with 21 per cent of moisture lost 0.4 per cent. It is my impression that if the lumber under test had contained 4 or 5 per cent of moisture, the absorption in transit would have been considerably greater and would have led to results which the author seems to have waived aside as possibly negligible. My own experience in testing a number of cars of lumber has been that apparently well-dried lumber will show 2 or 3 per cent of absorption, principally in the boards that are exposed, or near the top of the pile, or near the door. That is not a scientific statement, because of the crude way such tests are made in the trade.

R. K. MERRILL.[4] We experimented two or three years ago with dimension stock. These experiments are all filed away carefully in the permanent file, and have never been written up. When this paper came up, I was reminded of what we did in connection with kiln-dried dimension stock. It might be necessary for us to operate a mill; build a modern dry kiln; dry boards, and cut dimension stock very close to the source of supply, such as is being done by some of the body manufacturers. We wanted to find out whether these kiln-dried dimensioned pieces would pick up any considerable amount of moisture in a trip across the country, so we took several pieces and shipped them in freight cars, along with our finished product, to Los Angeles and to New York City, with instructions to the warehouse men at the other end to enclose these pieces in oiled paper, which we sent along with them. We laid them open in the freight car, without any attempt to cover them up, and, in fact, on top of the pile of material in the car. The pieces were then shipped back, enclosed in the oiled-paper container, and were tested when received. The results showed that the samples had not absorbed in excess of one per cent of moisture, based on the bone-dry weight. We were convinced from that that we could safely ship kiln-dried dimension stock to the seaboard, if necessary, and there assemble it without very much greater deterioration than it would experience in allowing it to stand around in the factory.

PAUL H. BILHUBER.[5] I have made extensive tests as to the gain in weight of lumber due to moisture absorption. Stock for cabinet work that is dried down to 5 and 6 per cent of moisture will gain about 2 per cent of moisture in the shop before it is in the finished article. In summer weather, or wet weather when difficult to keep the windows closed, there is the greatest gain; it averages about 2 per cent. In winter weather the lumber will sometimes stay at dry weight; especially if in a dry part of the

factory where there are process kilns, or warm boxes, or something of that kind. Five or six years ago we bought Pacific Coast stock for a particular piano part, and specified kiln-dried, 6 per cent stock. To the best of our knowledge the stock was so dried. When received in New York, the shipment time varying from 4 to 8 weeks, we noticed a gain of 2 to 3 per cent in moisture. Shipment was by box car. This is a much greater gain than has been indicated here by either Mr. Merrill or the author.

D. J. McLaughlin.[6] Mr. Perry's remarks are quite interesting to me because of an experience that I had some time ago with the Wood Mosaic Company, in connection with their Victor contract.

The Wood Mosaic Company kiln-dries lumber to 3 per cent moisture content, and it has been found necessary to paper the cars in order that the material could be used without redrying when received.

Experience has shown that different materials pick up from 2 to 3 per cent of moisture between Louisville, Ky., and Camden, N. J. The wood referred to was chestnut, and to my mind this bears out the argument that different kinds of wood pick up different quantities of moisture in transit under equal conditions. The soft wood picks up more than the hard wood.

# The Need of Research on Tropical Woods Before Marketing Them

By ARTHUR KOEHLER,[1] MADISON, WIS.

*After establishing the value of research in woods over cut-and-try methods of determining their properties and values, the author discusses two main lines of research which should be carried on with tropical woods, the determination of the normal properties of the species of wood, and the determination of means of overcoming objectionable qualities that may appear in the species.*

To talk about the need of research on tropical woods before trying to market them on a large scale may seem a bit like overdoing the modern trend toward scientific exactitude, especially when we consider that man had learned to use all the important European and American woods with a considerable degree of efficiency before the word "research" ever was heard outside of learned halls. Ordinary common sense suggests the question, why can we not go ahead and import new species of timber from the tropics and find out what they are good for, just as our forefathers found that hickory is the best wood for handles, cedar one of the best for fence posts, and white oak one of the best for wagon gears, before any scientific tests ever were run on these woods? Scientific common sense answers that we can, but that way of going at it is too slow and costly. How many birch, beech, maple, and other kinds of handles were broken in use before it was discovered that hickory was better? How many spruce and basswood fence posts rotted out in short order before it was realized that they are not so durable as cedar? And how many wagons broke down on the highway on account of having used unsuitable woods in their construction? It is a long story, the development of the use of the right kind of wood for the right purpose, some of it dating back to the dawn of civilization. Even yet the story is not complete, for we can find any number of cases of the wrong kind of wood being used for specific purposes, or of whole industries being guided by prejudices which have no foundation in fact.

Research furnishes data more quickly than cut-and-try methods. There is nothing mysterious or uncanny about research. It is simply systematized investigation. Instead of the so-called practical method (but in reality not highly practical) of trying this and that until a suitable combination is reached by the hit-and-miss method, research takes advantage of all the available information on a subject and then finds new facts to connect with what is already known. It is an interesting side-light on the progress of civilization that two such old and basic industries as farming and lumbering have much less research to their credit in proportion to their extent and age than some of the newer mechanical industries. Necessity, not initiative, is the mother of invention. Nor has the lumberman any brighter prospects ahead immediately, because the road to prosperity has not been paved with research; in fact, in some cases it is not yet known in which direction the road should be laid out.

In addition to furnishing data comparatively quickly, scientific research when properly carried on does away with guesswork and supplies facts. Good research is conducted under controlled conditions by men who are trained to observe carefully, to see small differences, and to make unbiased reports, whereas rule-of-thumb data are developed under varying conditions, often by untrained observers, and as a result usually lead to conflicting practice.

Finally, research is a capital investment. A piece of research properly carried out need never be repeated; it is not a recurring expense. Generation after generation can use it and build an addition to it without in any way impairing the value of the original structure. Knowledge once gained is good for all time.

## Main Lines of Tropical-Wood Research

In the study of tropical woods there are two lines of research which should be carried on:

1 The determination of the normal properties of the species of wood

2 The determination of means of overcoming objectionable qualities that may appear in the species.

## Determination of Normal Properties

Wood has more than a score of properties that are important in its utilization, among which are the following: weight, strength as a beam, toughness, stiffness, hardness, resistance to wear, stability, plasticity, durability, workability, nail- and screw-holding power, gluing characteristics, finishing characteristics, and heat insulating. For some uses a single one of these properties, as durability, may be of major importance, while for other uses a combination of several properties may be essential. Just a slight difference in properties may throw the balance in favor of one or another wood in specific cases. It is therefore essential to know what the properties of a species are so that a proper evaluation can be made of each species and each kind of wood can be used for purposes for which it is best suited.

Research on tropical woods is all the more important because practically nothing is known about most of them except what can be learned from natives and the uses to which they have put them, facts which often have little bearing on industrial uses in this country.

Whatever tests are made on tropical woods should be so performed as to yield direct comparisons between the new species and those with which we already are familiar. I mean tests should be conducted under the same conditions as to size of specimens, moisture content, etc., as govern the accepted tests of our American species. This does not mean that the tests must necessarily be made at the Forest Products Laboratory. Other institutions properly qualified and equipped could make comparable tests.

The comprehensive tests already made by the Forest Products Laboratory and others on native woods have paved the way for research on tropical timbers by showing which kinds of tests are the more important and how they should be made. It is out of the question at present to make as thorough tests on foreign species of wood as have been made on the important native species, and perhaps our institutions should never attempt anything quite so elaborate.

The following are some of the more important things that should be found out concerning the normal properties of tropical woods before importing them: (1) Means of recognizing each kind; (2) specific gravity of individual species, since it not only

[1] In charge, Office of Wood Technology, Forest Products Laboratory.

Presented at the First National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., October 17 and 18, 1927.

indicates the weight to be taken care of in shipping and handling, but it is also an indication of some of the other physical properties, such as strength and hardness; (3) actual strength values, by test, where the wood might be used for structural purposes; (4) ability of the wood to stay in place, which requires a knowledge of its tendency to shrink, swell, warp, and cup; (5) how the wood seasons in the open air and in kilns; (6) how it cuts into veneer; (7) how to glue it properly; (8) how easily it works under tools; and (9) what difficulties, if any, it presents in finishing.

How effectively a wood resists decay and insect and marine-borer attack and how it can best be treated with preservatives are matters of importance mainly for wood which is to be stored or used in damp places or where certain kinds of insects or other pests particularly abound. This question of durability applies especially to railroad ties, piling, and structural timbers, but there are many industrial uses in which it is of minor importance. For this reason, and because of the long time required to obtain full information on durability, tests of this nature could be omitted on tropical woods to be stored and used under conditions favoring immunity from destructive organisms.

### Overcoming Objectionable Qualities

The other line of research, namely overcoming handicaps, is a relatively new one with respect to lumber. It has been done with some species, notably red gum, which years ago had no stumpage value on account of its strong tendency to warp, but now is used in high-grade furniture because methods of drying have been developed which reduce warping to an almost negligible minimum. The tendency of many species to rot quickly also has been overcome by preservative treatments. There are many species, however, not only tropical timbers but among our native species, that have objectionable features not as yet overcome which now give them a relatively low value.

This is a tremendously important field. If the properties of a wood can be modified to meet certain needs, then its serviceability and value are at once greatly increased.

And why should it be not possible to modify the properties of wood? The properties of a multitude of other materials have been modified. The properties of cotton, for example, are changed considerably by mercerizing; the quality of steel is greatly modified by the admixture of small quantities of certain rarer metals as vanadium or tungsten; gasoline is given anti-knocking properties by the addition of tetraethyl lead; animal glue is made water-resistant by the addition of paraformaldehyde; certain foods can be given anti-rachitic properties by treatment with ultra-violet rays; salt is treated to make it less hygroscopic so that it "pours when it rains;" and the texture of Swiss cheese is controlled by inoculation of the curds with certain bacteria. Who knows what the limitations of wood are? Nobody knows because no one has determined its limits of usefulness if correctly handled.

Seasoning and application of preservatives are the only two processes applied on a large scale which change the properties of wood and make it better suited for certain uses.

One of the immediate needs in improving the quality of certain species is overcoming the raising of the grain on the surface after sanding. This one feature has given a black eye to numerous woods otherwise highly desirable.

A reduction in the shrinking and swelling of wood under normal moisture changes would overcome one of the chief handicaps of lumber for construction and manufacturing purposes. If the shrinking and swelling of wood could be reduced one-half by some kind of treatment, a new era would dawn in the use of wood.

Another need is some method of hardening the surface of wood by impregnation or otherwise so that the softer woods can be used for parts of furniture, musical instruments, interior finish, flooring, etc., in which a high degree of strength is not essential but a certain amount of resistance to wear and indentation is necessary.

Making the use of fire-resistant processes for wood more practical would overcome some of the objections to all kinds of wood.

A procedure very beneficial to producer and consumer of lumber alike would be to classify those species of wood which have a wide range in density into two or three density groups, each group suitable for certain uses.

Some species of wood are highly variable, so that it is necessary to know the range in properties and to make allowances in use accordingly. Mahogany is a good example. Some of it is so hard and heavy that it almost sinks in water when dry; other pieces are so soft that they are not suitable for exposed parts of furniture. By knowing their range in properties it is possible to classify such species of wood into groups suitable for different purposes. The heaviest groups might be best for substantial parts of furniture, the lightest might be used to best advantage for core stock, and an intermediate group might be just the thing for room interiors or parts of furniture not subjected to severe stress. This idea of grading lumber for intrinsic properties in addition to visible defects is a new one in industry, although grain, cotton, tobacco, and other products have been graded that way for some time. If species of wood could be sub-classified into groups in a practical way, the producer could sell each group to those interests requiring the properties represented by the group, in that way obtaining a more satisfactory market, and the consumer could get the particular quality that he desired.

These are only a few of the things that could be done toward obviating objections to foreign species of lumber—and to some of our native species as well.

One of the hindrances to the exploitation of tropical forests at present is that woods of many different species occur in a stand, of which only a few are of possible use and the others must be left, thereby increasing the cost of logging. By knowing the properties of all the common kinds in a particular region or country, the best uses for them could be ascertained, and by knowing how to overcome objectionable qualities, additional uses could be found. With such information more complete logging could be carried on in any given forest area of the tropics.

## Discussion

H. S. Fleming.[2] I am very much in accord with the author's proposal to have research work undertaken in respect to tropical woods and their treatment, and more especially in the matter of the treatment and handling at or near their point or origin with a view to determining means of avoiding the loss through checks and splitting which occur after the woods leave the humid atmosphere of the tropics and begin to dry out.

I especially commend the point that woods of many different species occur in a stand, of which only a few now have any commercial use, thus increasing the cost of logging, and that this situation might be greatly improved if the properties were known of the woods which have no commercial value. In my experience in the Amazon Basin, I found as many as 60 species of wood in one acre, and it is rare to find any considerable number of one species in a stand or within a reasonable distance of another of the same species.

H. P. Brown.[3] The utilization of the various tropical woods which are coming into this country, or which will be introduced in

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[3] Professor of Wood Technology, N. Y. State College of Forestry, Syracuse University, Syracuse, N. Y.

the future, hinges in no small degree upon a proper understanding of their technical properties. Fortunately, a routine schedule of research sufficient to determine the feasibility of the utilization of a given kind of wood for a specific purpose is already well established for our domestic timbers, and the author's proposal to pursue this same plan in research upon tropical woods is well taken. Standardization of research data, especially those of timber testing, is absolutely essential, even though these are at best only relative in their application. Not only is standardization desirable in the United States, but also between research centers in various countries, a fact which is already accepted in England and India. I believe that we who are interested in research upon wood can state, with all due modesty, that we are prepared to conduct such research on tropical woods in a manner satisfactory to the trade.

The successful introduction of tropical woods into this country, in my opinion, is less concerned with research, necessary as it is to determine their proper use, once here, than with the problem of their delivery into this country in sufficient quantity and of sufficient quality (to grade) to insure their general utilization. In other words, acceptance or rejection depends more on the quantity and the condition of the supply than upon the technical properties. This is rather a bold statement, but since wood lends itself to so many uses, surely some good can be found in almost any tropical timber unless prevented by price, quality, or the volume of the supply.

A few of the obstacles which the importer of tropical woods must surmount if he is to meet with success in his venture are discussed below.

1 *Prevention of Fungal Decay, Insect Infestation, and Marine-Borer Work.* The rapidity of fungal decay of wood in tropical-rain forests and at certain seasons of the year in monsoon (periodic rain) forests is always a source of surprise to one whose experience in this respect is restricted to the temperate zones. From my observations upon tropical woods I have been led to infer that it is practically impossible to ship some of the lighter, more perishable timbers any distance without serious depreciation from fungi, even though the sapwood is removed. Loss from this source could be materially lessened were proper measures employed in the jungle, but the importer must remember that he is dealing largely with illiterate, crude labor, and often with the silly superstitions of ignorant jungle folk. Moreover, in the tropics the boring insect is always to be found, and poor harbor facilities add to the difficulties, necessitating delays which encourage marine borers. Importers, therefore, must be prepared for disappointments.

2 *Lack of Sufficient Supply.* With the exception of the dipterocarps, which are restricted to the Indo-Malayan region, I know of no hardwoods which are sufficiently gregarious to form well-nigh pure stands. The problem of successful exploitation is therefore the harder to solve because of the many varieties of trees that grow on relatively small areas, as the author has already pointed out. The lack of winter snows which facilitate logging, of rivers to float out logs, and the fact that the logs of many species will not float, even after prolonged seasoning in the jungle, with its concomitant decay infestation, make lumbering the more difficult.

In many cases the absence of water transportation necessitates land conveyance, often over extremely rough topography, through dense jungle vegetation, and in regions where the tsetse fly prohibits the use of beasts of burden. Furthermore, the ignorance and conservatism of the workmen and the cost of introduction militate against mechanical carriers. In consequence the operator is often restricted to the use of man power to remove logs from the jungle—at best a slow and expensive process.

3 *The Lack of Trade Names.* Mr. Alexander Howard, one of the best-known tropical timber importers of Great Britain, has said that the name under which the wood is placed on the market is one of the most important factors which govern its successful marketing. Man is by nature conservative and loath to try anything new; consequently in order to introduce a new timber, the importer must anticipate a considerable outlay in advertising before his sales will justify operation on a large scale.

4 *Delay in Supply.* There is a lack of firms in the tropics, especially in the Far East, who carry stocks of timber other than of a few well-known species, such as teak, rosewood, etc., that is, woods with an already established world-wide reputation. If an order is placed for lesser-known woods, the reply that usually comes back is that the lumber can be supplied the next working "dry" season, generally six to eight months ahead.

5 *Insistence on the Use of American Grading Rules in Purchasing Tropical Woods.* Firms in the tropics with timber for sale feel that they cannot make the grade. In some countries they have their own grading rules; in others they have rules of but the crudest sort. In many cases the importer must cut the cloth to the subject; he must coin his own rules.

6 *Overestimation of the Timber Supplies of the Tropics.* The term "jungle" does not imply merchantable stands. There are thousands of square miles of tropical forests that cannot be logged at a profit under present conditions. In certain places excellent stands occur, but they are the exception rather than the rule. Weed trees of all shapes and varieties abound, and these reduce the general average of quality and increase the expense of production.

In conclusion, I hope I have not painted the picture too black. I believe in the utilization of tropical woods. Through research we technologists can find and devise uses for tropical timbers, but in my opinion that is the lesser problem in their successful introduction. Success or failure depends not upon finding uses for them once we import them into the country, but in getting them here sound, in sufficient quantity, and of reasonably standard grade and price for commercial purposes.

D. M. Matthews.[4] The waning supply of first-grade native hardwood, with the consequent increase of price, directs more attention every year to the search for substitutes; and substitutes other than wood, at greater prices than wood, and sometimes with less satisfaction in use, are being very generally adopted. It is not willingly that wood users are thus turning to other materials, but only because they can no longer obtain specific wood material in the grades, dimensions, and quantity that they require in their particular industry. Quantity is a very important consideration. Often a user might be willing to accept a wood which he did not consider quite the equal of the material he had been using previously, if he could only be certain of a steady supply of this wood in the quantities which he requires annually.

If the substitution of other materials for wood is to be checked, and if the wood-using industries are to continue their development along the lines for which they are organized, new sources of supply for hardwood will have to be tapped. The only undeveloped source of supply lies in the tropics and, with the exception of such generally used woods as mahogany, teak, and other rare cabinet woods, the timber species which make up the bulk of these tropical forests have only been abortively marketed in temperate regions and less in the United States than elsewhere. We are now in the "cut-and-try," "rule-of-thumb" period with regard to them. Research along the lines suggested by the author is the only way in which we are going to reduce the period of hit-or-miss experimentation so that the tropical-wood resource can be made available in time to take up the slack between the

[4] Professor of Forest Management, School of Forestry and Conservation, Uni rsity of Michigan, Ann Arbor, Mich.

exhaustion of our present native supply and such time as we may be able to grow sufficient to supply at least a portion of our current requirements.

General research to determine the normal properties of any new wood is, as the author points out, a prime requisite, but I am especially interested in the second line of research he mentions, namely, "the determination of means of overcoming objectionable qualities that may appear in any species." The wood-using industry of the United States is, in this day and age, more specialized than ever before and than anywhere else in the world. We use a minimum of labor and a maximum of machinery, and speed is the "essence of the contract" all along the line. This specialization calls for very specific qualities in the woods which we put into use, and slight variations from these specific, standard qualities often cause the rejection of a wood for a specific purpose. Abroad new woods come into use more easily than they do here. In other countries users are willing and able to modify their methods to meet the species. We are generally unwilling to do this, and the suggestion that research may help us to modify the wood to meet our methods is a welcome one. There is a wealth of valuable prime-grade hardwood in the forests to the south of us, but it is unlikely that we shall find many woods, in quantity, which will exactly meet the specifications of woods which are in general use here. Many will be close to native woods in general use, may have qualities which are superior to this characteristic of the native wood, but be turned down because some minor point differs from the native wood in use. I had a very concrete and vexatious example of a case of this sort when exporting timber from Borneo to Australia. We have in Borneo a timber called "kruin," one of the larger dipterocarps, known as "apitong" in the Philippines. We considered it a very fine flooring material and, as we manufactured by hand there, we had no difficulty in working it. We sent samples to Australia. Our friends there were very much taken with the wood, considered it superior to any of the floorings they were getting from elsewhere at the price, and placed an order for several hundred thousand feet of blank flooring stock, intending to tongue, groove, and plane it there so as to avoid duty on finished wood which the Australian tariff imposes. The wood contains a very considerable amount of oleo-resin which, unless the material is very thoroughly dried, will appear on the surface of planed stock for a time. With our slow methods of manufacture this never bothered us.

The Australians proceeded to put our stock through very high-speed planers and matchers which they had been using for Douglas fir. They could not handle it. It dulled the knives; they chattered and produced a rough surface, and the temporary stain of the resin appeared on the planed surface. As a result they refused to accept the shipments. The distance was too great for it to be shipped back, and a 50,000-dollar arbitration case arose which threatened to go to the courts with no one knows what additional expense. We were four years in getting the matter settled, and the firm I was with lost the Australian market. We have since found out that adequate steam kiln-drying removes this objection entirely. Had we known that at the time, we should have saved many thousands of dollars, and a steady trade in the timber would have continued between Borneo and Australia. This is a practical example of how research along this line, as proposed by the author, is going to permit specialized methods and machines to take new woods and put them into use.

Another point in the paper which seems to me of great importance is the proposal to classify tropical species into groups suitable for different purposes. This is a step in the right direction, whereas producers of tropical timber have been too long moving in the opposite direction. The redwood produced by various species of "shorea" in the Philippines, Borneo, Dutch East Indies, and Federated Malay States is marketed in the East under a host of local names, and elsewhere as Philippine mahogany, Borneo mahogany, Borneo cedar, Pacific maple, etc. This is not only unscientific but it is bad business practice. There are enough different woods in the tropics without multiplying them, and yet one firm that I know of has been adding trade names in the hope that they will get all the business in a certain wood to themselves, although the same wood was produced in all the countries mentioned above. This was a very short-sighted policy as the markets where they were placing their product could have taken much more of the wood than they could produce, and the development of a general market was retarded. As the author suggests, we need to group woods of different names but of similar qualities so that quantity production is possible. This will reduce the costs of production and assure steadier supplies to the consumer. However, such grouping must be scientific and based on adequate data as to the characteristics of each species. Such classification should be based on sound research—it cannot be left to the producers themselves, for they have already shown a tendency to move in the opposite direction.

So much for the research into the qualities of the woods themselves. The author has shown that it is a very necessary prerequisite to successful marketing. I would only like to add that research, or exploration if you like to call it so, of the sources of supply of the tropics is an equally needed piece of work, and the information so gathered should accompany the publication of the results of the research on the qualities of the woods themselves. When I was conservator of forests in Borneo I was anxious to have some authoritative data prepared as to the strengths and general qualities of our more important timber species, and I had this work done at the University of Hongkong. When I received the data I handed them over to the lumber companies. They apparently sent out small samples of the various species to all of their agents and customers with labels attached quoting all the more favorable data with regard to each species, but without stating what sizes or quantities could be supplied. Later on I became manager of the largest lumber company in Borneo, and I was more than once embarrassed by firm orders for quantities and sizes of various species which were entirely out of the power of my company either to produce or deliver. I remember one order for 20 spars of Borneo ironwood to measure 96 in. in circumference at the center and 110 ft. in length. As the species rarely has a clear length of over 30 ft. and a diameter of over 24 in., I had to regretfully decline the order. Moreover, as the wood weighs about 90 lb. per cu. ft., the spars would have weighed about 20 tons each if we could have produced them—I don't know how we would have shipped them.

Therefore in our efforts to bring the useful timbers of the tropics into use in this country we must be equipped with a knowledge of the sources of supply and concentrate research on species which can be produced in sizes that will meet market demands and in quantities which will enable industry to standardize with them in use.

The examination of the sources of supply in the tropics should not stop with the mere determination of what species were present in abundance. The accessibility of the larger timber supplies, both as regards transportation to the consuming centers in this country and with respect to extraction costs of the timber in the forests themselves, should be determined and determined in detail, at least for a few strategic points. Utilization plans for a few tracts of a couple of hundred thousand acres each, showing what it would cost to log, mill, and put the finished product down f.a.s. at regular points of call for steamers plying between Central and South America and the United States, are needed so that we may know what species can be produced in quantity and at a cost which will permit industry in the United States to plan for their continued use. In other words, I feel that research into the

specific qualities of tropical timbers and the determination of how they can best put into use in this country should be backed up by information as to probable available supply, dimensions in which the supply can be delivered, and costs. Without this information research cannot concentrate on the important problems, and we need it concentrated on the species that we are going to be able to get in quantity at reasonable costs.

T. H. Gill.[5] The following comment and suggested program is the result of a recent conference with Samuel J. Record, Professor of Forest Products in Yale University.

It seemed to both of us that although there can be no question as to the desirability of more or less elaborate tests on various tropical species, there is strong reason to doubt that such tests will be undertaken in the immediate future. It seemed, too, there might be a place for an interim program which would not only expedite some more elaborate program but which would recommend itself because it could be begun immediately and with relatively small funds.

This program which we thought of as an interim program is by no means intended as a substitute for complete tests that may ultimately be needed. It is rather a suggested means for obtaining immediate results and answering some of the questions regarding the practical possibilities of certain tropical species.

The interim program proposes the formation of a committee with the following three functions:

1 Decide on the species to be tested and the nature of the tests
2 Arrange for the tests with woodworking plants or other agencies
3 Acquire information on the availability, abundance, and local uses of each species.

The working out of this plan would be somewhat as follows: The committee will seek the cooperation of woodworking plants willing to take one or two selected species and give them such practical tests as in the routine of their work they are best fitted to give them. Preferably parallel tests should be made by sending specimens of one species to two or more plants. After an examination of the species the committee will decide to which plants they should be sent and the nature of the tests. It will also be responsible for correlating the results.

If in the light of these practical tests it seems desirable to make further tests for certain species, the work could be modeled on the procedure of the Imperial Institute of London. Tests there are made for sawing, planing, boring, nailing and screwing, gluing, and polishing. Mechanical tests include static bending, compression, shearing, cleavage, tension perpendicular to the grain, hardness, specific gravity, moisture, and weight per cubic foot. These tests are sufficient for nine-tenths of the species and involve no great cost. Of course the important thing is for the industry itself to decide on a wood; and in order to learn the fitness of a wood for specific purposes, the wood should be tried out for those purposes.

In addition to the tests, information regarding the occurrence and local uses of the various species could be obtained from field workers in the tropics. I myself hope to collect within the next three years a deal of data on the range, availability, and uses of the more important species throughout the American tropics.

The above plan would seem to combine the advantages of an immediate start and an adaptability to investigation on any scale that funds may dictate. If very little money is available a start could still be made by experimenting first with species now offered for sale but not yet established on the United States market. The promoters of these would undoubtedly provide specimens for testing purposes. Later the tests could be extended to other woods. British Guiana has recently reorganized its forestry department and is making a survey of available timber areas with a view to getting all information concerning her little-known but potentially important woods. The forester's report for 1926 indicates that they would be willing to supply material for testing.

The program means a definite start toward answering some of the questions that must be answered before the industry will accept new woods—it provides a way of establishing satisfactory species to take the place of those that because of their scarcity are now becoming costly, difficult to obtain, and open to the increasing inroads of wood substitutes.

Willard Winslow.[6] It seems to me, from the point of view of a tropical lumberman, that the value of scientific research in connection with tropical woods is a secondary consideration.

The natives using these woods have long ago worked out, from experience, the standing of tropical woods, as to durability, workability, and the other facts that the author states are important. I should put the factors necessary for the successful use of tropical woods in the following order:

1 Whether the stand of timber is large and uniform enough to make lumbering practicable and not too expensive
2 Whether the woods imported can successfully compete with woods now in use, even allowing for a steady advance in price
3 The climate, freedom from diseases, stability of government, and labor supply
4 Existing or probable means of transportation
5 Scientific research in these woods, as to their suitability for special purposes, after a possible market is established and the other difficulties overcome.

In Manila, Hongkong, Shanghai, and Yokohama the native workmen are satisfied to get hold of small quantities of valuable hardwoods in the log. These woods are sawn and manufactured by hand, and it is not necessary to duplicate a wood to introduce it.

To interest capital to manufacture or log a tropical wood, it must be shown that there is a sufficient accessible volume of several good woods and a large and continuing supply. Also, all the other favorable features which I have mentioned must exist. The absence of any one of these factors would preclude any considerable investment.

To spend the time and money required for scientific research as to the value of tropical woods is a waste of time and money if these woods cannot be obtained in commercial quantities and a steady supply. Any experienced tropical lumberman can tell at once whether the necessary factors are present and whether the wood is suitable to substitute for our vanishing domestic woods.

For example, there is a wood in the Philippines that appears to be a substitute for lignum-vitae, but tests of this wood for tail blocks in ships prove that it is not, as it lacks the oil contained in lignum-vitae. There are several tropical woods that appear to be a substitute for dogwood for shuttles, but tests show that they lack the grain of dogwood and "check." Many substitutes have been tried for pencil cedar, but each one is lacking in some special quality.

The author speaks of "scientific research showing that mahogany was useful for various purposes." The foreman of any factory can tell in a day whether a mahogany is suitable for his work, even if he has never seen it before. The log importers in London and Liverpool can not only tell at a glance what the

[5] Forester for the Tropical Plant Research Foundation, Washington, D. C.

[6] Indiana Quartered Oak Co., Long Island City, N. Y.

wood in question is, but can even tell with certainty from what particular ports of the world the logs came.

The author speaks of scientists sub-classifying mahogany, so that the producer could sell "each group to the proper interests." This is the a-b-c of the mahogany business, and for the past 25 years mahogany has been sorted for special work, and even manufactured to suit special needs.

It is not a generally known fact that the wood of the same tree varies, as well as the wood from different trees of the same species. This selection of wood has been carried to a fine art in the manufacture of high-grade pianos. For example, in the manufacture of the best-known grand piano, spruce was selected with not less than thirteen grains to the inch, as it has been found that slow-growing wood has the most resonance. The maple also used in the case is selected on account of its resonance. The white pine for keys is selected three times, to insure the key's remaining perfectly true. In the manufacture of fast motor boats, where the reduction in weight of the boat is a matter of pounds without sacrificing strength, experience has determined the special mahogany required for each part.

I mention these facts at the risk of redundance to show that scientific research cannot be of any aid as against years of experience. Our forefathers knew perfectly well that a cedar post lasts longer than spruce, but they used spruce when they could not get cedar and not because they did not know better.

The Philippine Malay used Philippine mahogany 350 years ago for planking boats, because he had found that it was the most suitable wood he had. My somewhat extended experience with boats in different tropical countries has led me to the conclusion that the native has found out what is the best available wood for his purpose invariably, and the man who uses the wood knows better than any one else its qualities and defects.

During the past 40 years I have exported large quantities of white pine to ports of the West Indies and South America, where mahogany was used for railroad ties, fences, and hog pens, and where forests of much better woods for their purpose grew all around them. The reason for this is that there were and are no sawmill facilities or transportation to make these forests available in any volume.

Probably the greatest available hardwood forests in the world today are in the Philippine Islands, and yet there are some 26 abandoned sawmills scattered among the Islands. The reason for this is health conditions, lack of labor, capital, transportation, or local markets for the low grades. Ask the investors who were stung!

At the present time foreign corporations cannot compete with local Chinese loggers and lumber yards when it comes to transporting and manufacturing a great number of scattered but valuable and handsome hardwoods. These bring a higher price in their local markets than the most valuable foreign woods imported into the United States.

After overcoming the many difficulties in obtaining a valuable tropical wood in commercial quantities, and establishing a market, we might then avail ourselves of the services of the Madison Laboratories in assisting us to confirm what experience has worked out, especially where the wood is to be used for a very special purpose. If experience proves a wood satisfactory, its botanical status is of no interest to any one but the dendrologist and the nurseryman.

G. P. Ahern.[7] The author brings out clearly the need for systematized investigation in the search for suitable tropical woods to meet our needs. We all know how difficult it is to market a new wood. A wood may have very desirable properties and the price may be satisfactory, but there will be a lack of interest if there is no real guarantee that adequate supplies of such wood can be maintained over a period of years. Scientific research can tell the story of stand and distribution of promising tree species. But preceding the search for suitable foreign woods must come an analysis of wood needs to show:

(a) The specific properties requisite to the various industries
(b) The quantities required by each industry and the extent to which native species will fail of meeting requirements
(c) Range of prices within which new material must be supplied
(d) Definition of qualities which new species must present to meet the requirements of various industries.

With that information, which is now being prepared, we shall seek woods that must meet requirements.

The Main Research Committee of the A.S.M.E. very wisely suggested at the beginning of this project a year ago that as a first step it would be necessary to prepare a bibliography of tropical woods, thereby making available the world's literature on this subject. The first edition of such a bibliography was prepared and several hundred copies issued late in 1926 to persons and organizations interested, including wood experts in some 36 foreign countries.

With each copy was sent a letter explaining the project and requesting cooperation in the preparation of a more complete second edition. A very general and helpful response indicated keen interest and gratification that such data would be collected for the benefit of all. These wood experts have furnished many useful data which will make the second edition, soon to be published, more complete than the first. In addition, the cooperation of these experts now assured will be most helpful following the coming field investigations, when promising tropical-wood specimens are furnished the laboratories and factories for testing purposes. All available information concerning the properties of a wood will be very helpful to the laboratory man or the factory superintendent.

Our Philippine experience will be helpful in this project. Many of the difficulties in the present situation were present in the Philippines 25 years ago, when United States woods were transported 6000 miles across the Pacific to supply the construction needs of the Islands. Field investigations developed the fact that in the 60,000 square miles of Philippine forest, some 20 of the 3000 tree species found there constituted 80 per cent of the stand. That figure holds good to this day. A majority of the 20 abundant species were considered unsuitable to market needs, and some of them could not be sold at any price. A government laboratory and a government workshop developed desirable properties in these abundant but unpopular woods which today find favor in the markets of some fifteen foreign countries.

It requires cooperation in support of a properly equipped organization to make the preliminary investigations as to sources of supply and to conduct researches necessary before new species of wood can be brought into use where they are required and in the quantities demanded.

Great national or world needs of this character are often neglected by governments and industrial organizations until some pioneer with vision blazes the way. Thanks to the Charles Lathrop Pack Forestry Trust, a fund has been provided for a three-year program of tropical-forest research. This trust fund has for its general object the advancement of forestry in the United States, but the Trust recognizes that the timber-producing capacities of the tropics are both a domestic and a world problem. The Tropical Plant Research Foundation of Washington, D. C., has foreseen the necessity of such work, and is prepared to undertake it.

A fact-finding expedition financed by this Trust Fund will be

[7] Tropical Plant Research Foundation, Washington, D. C.

sent by the Foundation to tropical America early in November, under the leadership of Forester Tom Gill. The forests of the Caribbean region will receive attention during the first year. Eventually the expedition will visit all tropical American countries whose forests are of commercial significance. The field of investigation will furnish information concerning:

(a) The location of accessible bodies of timber
(b) The quantities and sizes and distribution of various important species
(c) How these species are being used at present
(d) Primary costs of extraction and milling and approximate costs at which logs or lumber can be laid down at American ports.

The present program of this Foundation survey provides for securing information on tropical woods but not as yet for collecting logs for testing nor for making scientific tests and factory trials of the woods in this country.

It is hoped, however, that additional cooperation may still be secured to defray the cost of securing timber samples, transporting them to the United States, and testing them at the Madison Laboratory or in other institutions.

The following points concerning these woods require attention:

(a) Their definite structure and identification
(b) Their general mechanical properties, strength, durability, workability, seasoning possibilities, finishing, and possibilities of overcoming objectionable qualities
(c) The correlation of their determined properties with uses in the United States
(d) Factory demonstration tests supplementing laboratory investigations.

The story of the local uses of tropical woods, especially of the abundant woods, will not necessarily have a bearing on our industrial uses, but will serve as a hint in conducting tests. Elaborate laboratory tests will not be feasible, due to lack of funds for that purpose, but sufficient information will be made available in advance of tests so as to point the way toward the most promising and most desirable uses of each wood tested, thus saving more or less time and effort. The woods that have stood long-time tests in the tropics in the manufacture of spokes and rims, wagon poles, tool handles, railroad ties, musical instruments, etc., are worthy of study, especially if these woods occur in quantity.

Carelessness in logging and delays and neglect in handling logs exposed to tropical sun and rain account for unfavorable reports as to useful properties. A very different story may be told of such woods when not so handicapped but collected and cared for properly, botanically determined, and definite information gathered concerning stand and distribution, as well as possibilities of extraction and shipment.

The experiences in the past arising from disputed nomenclature of tropical woods coming into our markets (the Philippine mahogany case a recent example) should be a warning of other disputes likely to arise as tropical-forest exploitation expands. As new tropical woods come into the market, some efforts should be made by wood technologists toward standardizing methods of their analysis and description, and with importers, wood users, and others interested arrive at agreement on some scheme for classification.

It is quite possible that logs can be laid down in quantities at attractive prices and manufactured in our hardwood mills without disturbing the hardwood market. A number of hardwood mill companies of the Gulf States are becoming more and more interested in this tropical field; some are looking into the possibilities of securing forest tracts; others are making arrangements for shipments of logs. This development will tend to remove one of the most serious phases of the opposition to imported hardwoods just mentioned. In any event this entire movement toward the development of tropical forest resources will move slowly, and at a rate dependent largely on market demands. The many handicaps in the road will take years to remove. In the meantime research will provide accurate information to meet the needs as they arise.

D. H. Allen.[8] A necessary preliminary to tropical research would seem to be the preparation of a list of domestic woods for which substitute species are needed either by reason of the high price of the domestic wood or because of its inferior grade.

Much wasted effort and expense could be saved if a list could be prepared of the principal domestic woods for which substitute species are needed: This list, to be a helpful guide to tropical research, should include information as to the board footage of the wood consumed by the American market, the principal uses of the wood, the principal properties and characteristics which would be required in a substitute, the approximate average dimensions of f.a.s. selects and No. 1 common in the domestic wood, and whether the consumer could afford to pay a premium for larger average dimensions in a substitute wood, whether the demand is primarily for $^{8}/_{4}$ and thinner or whether there is a large demand for thick planks, whether pin-wormy lumber in the substitute wood could be used for some purpose, whether the wood is used both for lumber and veneer and if for veneer whether for rotary cutting or slice cutting, and finally the present prices at which grades of No. 1 common and better are being sold.

It is desirable to have in mind that tropical hardwood trees as found in virgin stands have greater diameters and lengths than most domestic hardwoods. For this reason it is easier to obtain from tropical hardwoods lumber of large average width and length than from domestic hardwoods. Furthermore, the predominant defects in tropical hardwoods differ from the defects found in domestic hardwoods. In tropical timber the principal defects are usually pin worms and heart defects, whereas in domestic hardwoods the principal defects are usually large, scattered knots. As a rule it is easier to obtain clear boards of large dimensions or clear thick planks from tropical hardwoods than from domestic hardwoods, so that wherever lumber of this type commands a premium, the tropical wood has an advantage. With the exception of the Philippine Islands, tropical logging is selective, i.e., trees of certain species are located and hauled out of the forest, but no attempt is made to utilize the forest as a whole. This process of selective logging is necessarily expensive. For this reason it would seem wise at first to concentrate upon finding substitutes for domestic woods having an average sales value of $100 per thousand board feet or higher for grades of No. 1 common and better.

If it is found possible to market in this country a number of the common species of tropical woods, the cost of logging could be materially reduced because of the increased yield per acre of forest worked.

As soon as those interested in tropical woods are placed in possession of information as to the types of wood for which substitutes are needed and the price at which the substitute wood can be sold provided it has the desired characteristics and properties, arrangements can easily be made for bringing in sample shipments of woods having the general characteristics desired. It would then be necessary to arrange facilities for laboratory tests to compare the proposed substitutes with the domestic wood. If these tests showed the substitute wood to have real promise, it would be desirable to have the principal consumers

[8] President, Astoria Importing & Mfg. Co., Inc., Long Island City, N. Y. Mem. A.S.M.E.

of the wood concerned arrange to make practical tests of the substitute.

It is well known that certain tropical woods have special qualities which no domestic woods possess. There are in all probability consumers looking for a wood with special qualities but they are unaware that such a wood is available and are therefore using an unsatisfactory wood or some other substance.

For example, there are known to be tropical woods which are very hard, very heavy, and extraordinarily durable under the most trying conditions. These woods are expensive to bring out and expensive to manufacture into lumber, and the price at which the lumber would have to be sold would seem prohibitive except for some special purpose. On the other hand, it is quite possible that certain consumers would be glad to pay a comparatively high initial cost to avoid constant replacement where replacement is difficult and expensive. It is necessary, however, that those familiar with tropical woods should know of the special need in order to fill it.

In brief, there are thousands of different woods in the tropics exhibiting a wide range of wood properties and characteristics. The easiest, quickest, and least expensive method would seem to be to ascertain first the type of wood that is needed and the price at which it can be sold, and then search for a wood of that general type in the tropics. Otherwise it is necessary to bring in thousands of samples of woods in the hope that out of the number some may be found which will prove satisfactory substitutes for domestic woods and can be sold at a price to compete with domestic woods.

H. M. Curran.[9] My own experience, covering many years of exploration and exploitation of tropical timbers, has convinced me that the timbers the world needs exist in large quantities in the tropics, can be produced economically, and that the price levels are at present such that the better grades can flow into our markets without prejudice to our timber business.

These interests will be benefited rather than harmed by these tropical timbers, for they will flow through their mills and sales organizations, helping them to retain their markets against substitutes. There need be no fear by American lumbermen that these timbers will replace the well-known woods of America.

Less than 20 per cent of the product of a tropical mill will probably be exported, and this only high-grade. The remaining 80 per cent will enter the channels of trade in the country of its origin.

# Our Need for Knowledge of Tropical Timbers

## Rapid Waning of Supplies of Virgin Timber in This Country Calls for Extended Use of Tropical Woods, Whose Properties and Uses Must Become Familiar to the Industry

By SAMUEL J. RECORD,[1] NEW HAVEN, CONN.

WHAT interest has the American lumber industry and American forestry in tropical timbers and forests? Of what advantage would it be to our nation to have reliable information concerning the forest resources of our southern neighbors? If lumber from foreign sources is a potential competitor of the produce of our own sawmills, why not make stronger the barriers of ignorance and prejudice rather than try to break them down? Why should the School of Forestry of Yale University have any concern in these matters outside the realm of pure science? And why should The American Society of Mechanical Engineers consider the problem of tropical woods worthy of serious consideration?

To those familiar with conditions the answers seem obvious. Our lumber industry, in its manifold ramifications, is one of such vast and fundamental importance to the prosperity and general well-being of our nation that any thing that affects it affects the welfare of all our people. If this industry is imperiled, it is the duty of those who sense the danger to raise their voices in warning and to take such other measures as are within their power to anticipate any emergency and reduce the seriousness of its effects. Those in the best position to know believe that our lumber industry is now facing such an emergency as a result of the prodigality with which it has been consuming its raw materials without adequate provision for their replacement.

Warnings of an approaching timber famine have been given many times in the past, but changing conditions, especially the extension of transportation facilities into more and more remote localities, have postponed the day of reckoning. An unfortunate economic situation, particularly with reference to excessive taxation of standing timber, is forcing the too rapid cutting of the remnants of our virgin forests, and the resulting abundance of lumber on our markets gives the false impression that there is a corresponding abundance of standing timber.

### The Timber Situation in the United States

The timber situation of the United States has been made the subject of careful investigation by our Federal Government. The whole expanse of our country is known, its forest resources have been inventoried, and the factors of increase and decrease calculated. It requires no gift of prophecy to check our outlay against our forest capital and income and compute the result. The agency best qualified to do this is the U. S. Forest Service, and in this connection attention is called to a highly informative article by Chief Forester W. B. Greeley, entitled, "The Relation of Geography to the Timber Supply."[2]

> Most of the industrially aggressive nations [says Mr. Greeley] have lived in forested regions, and most of them have been liberal users of timber. The course of these nations in satisfying their requirements for forest-grown materials has usually run through three different stages. At first they have cut freely from their own virgin forests as long as the supply lasted. Then they have cast about for what they might barter from their neighbors. And finally they have settled down to the systematic growing of wood on all the land that could be spared for the purpose, still finding it necessary or convenient in many cases to import a substantial part of their national requirements from other countries whose virgin forests have not yet become depleted or whose timber culture produces an exportable surplus. . . . .
>
> The United States is still in the first of these three stages. By far the greater part of the wood we use is still obtained from our own virgin forests. But the end of this supply is plainly in sight. The necessity is at hand of finding a new source of wood, either in timber culture on our own soil or in the forests of other countries. The consumption of timber in this country is so enormous that the problem assumes staggering proportions. We use annually about 12 billion cubic feet of saw-log timber, or nearly half of the quantity consumed in the entire world. Our use of all forest products, including pulpwood, railroad ties, mine timbers, and fuel wood, aggregates $22^1/_2$ billion cubic feet, or about two-fifths of the yearly consumption in the entire world.
>
> Other countries which have likewise exhausted their virgin forests have found new sources of wood either in the practice of forestry or through imports from their neighbors or by combining both of these methods, without sudden industrial upheavals or serious timber famines. Their consumption of forest products has been relatively small; the change was gradual and usually involved no great difficulty. The enormous use of wood in the United States, however, and its intimate relation to national living standards, manufactures, and basic industries like agriculture, mining, and transportation, make our problem far more serious. We must find, almost overnight, a fresh source of raw material sufficient to supply 60 or 70 million tons of forest products annually. Instead of a gradual industrial evolution, the change is coming with the suddenness of an economic crisis.

Further along in the same article he says:

> The stern facts of geography have largely controlled these past developments in our forest industries and in the cost of their wares to the American consumer. The true measure of timber supply is not quantity but availability. Sixty per cent of all the wood that is left in the United States and 75 per cent of its virgin timber lies west of the Great Plains, whereas two-thirds of the population and an even larger proportion of our agriculture and manufactures are east of the Great Plains. The forests bordering the Pacific Coast contain over a trillion board feet of virgin stumpage. At the most, they will not supply our present consumption very long; but already the unbalanced geographical distribution of this resource is creating well-nigh famine prices in the parts of the United States where forest products are used in the largest quantities.

Of course the ultimate solution of our timber supply is to be found at home where there is an abundant supply of land which can be and should be devoted to forestry practice. We must look to the time when lumbering is stable rather than nomadic, when timber is cropped rather than mined, when our now idle lands are keeping our wood-using industries supplied and keeping thousands of people in permanent employment. These are ultimate aims, but what of the immediate future? How are we going to meet "the change that is coming with the suddenness of an economic crisis?"

It is interesting to note that foremost of the suggestions the Chief Forester makes in this connection is that "we must get all the foreign wood that we can to tide over the lean years, and we must go after it intelligently and systematically. For one thing, a thorough study should be made of the resources available in the hardwood forests of Central and South America, and their utility for the replacement of our rapidly waning supply of native hardwoods."

### Need for Identification and Classification

Here then is a very definite task at hand for those who are will-

---

[1] Professor of Forest Products, Yale University.

[2] *Economic Geography*, March, 1925.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, February 24, 1928.

ing and qualified to do it. My own interest in it began back in 1916 when the Yale School of Forestry extended its field of endeavor to the tropics, particularly tropical America. It has been pioneer work in a vast region with one man, at the most two, with very little assistance of any kind and very limited funds, hence you will appreciate how far we are from having exhausted the subject! In fact, to be able to make any appreciable showing at all it has been necessary to emphasize special lines of work, particularly the identification and scientific classification of the trees and woods. While on first thought this may seem to be only of academic interest, as a matter of fact it is fundamental. Of what use are reports on woods unless one knows exactly what woods are meant? To thread the maze of vernacular and trade names requires patient and painstaking research, often extending over years and requiring many collections of specimens from the living trees in the forest. Timber cruisers in strange forests are largely dependent upon native guides for the names of trees, and when one takes into consideration the various languages and dialects spoken even in the same locality, the anxiety of the guides to be accommodating to the point of invention, and adds to it the cruiser's attempts at phonetic spelling, the only surprising thing is that the reports are at all intelligible. The wise cruiser brings out wood samples and other specimens for identification. Such specimens not only show what kinds of timber are there, but also, if properly determined, give him the benefit of all the information that is available about the same or closely related species from other localities and countries, and frequently point the way to the proper market.

The question of the correct naming of woods is of far-reaching importance. The introduction of new and untried timbers into our market is usually a slow and expensive process, and the temptation is always great to resort to subterfuge and deceit. Those who stoop to mislabeling their lumber are blind to their own interests, because no business founded on abuse of confidence can long succeed. Many a wood which could have won favor on its merits has suffered irreparable injury because its promoters forced upon it the reputation of an impostor. Until foreign woods can be brought in and sold for what they are, they should be kept out, since misappropriation of a valuable trade name is unfair competition and serves to degrade the whole lumber industry.

The tropical woods available for introduction in quantity into this country represent a wide variety, but for the most part they are not in the high-grade furniture or cabinet-wood class. The popular conception that all tropical woods are hard and heavy, or finely figured, or noted for their beauty of grain and color, is all wrong. The abundant kinds are the commonplace ones, useful but often not beautiful. They are called hardwoods to distinguish them from the pines and spruces and cedars which are called softwoods, but some of these hardwoods are lighter than cork and as soft as the pith of a cornstalk.

Tropical woods are for the most part of species and tree families different from those with which we are familiar. Beech, birch, maple, hickory, ash, and the other kinds we know so well and upon which our hardwood industries are built, do not grow in the tropics. One may find oak and certain other temperate-zone trees within the tropical belt, but mostly only at high altitudes. There is pine in Mexico and portions of Central America, and the lumber can enter our market without difficulty because the trade is familiar with pine and knows how to size up a new lot very rapidly. When it comes to judging tropical woods by American hardwoods the situation is more complicated because the new kinds are different. Being different, however, implies neither inferiority nor superiority: it merely means that some time and effort must be given to acquiring the information necessary to successful utilization. If the same trees grew in the forests of the United States they would be utilized as fully and in many instances as satisfactorily as are the ones actually here.

There are many problems involved in the introduction and utilization of unfamiliar woods. There are two ways of going about a solution. One is the slow, wasteful, and haphazard method of leaving things to chance and individual effort. The other is through the cooperation of various scientific agencies and trade interests. The latter method will give results quickly, and the knowledge gained will be of service to our lumber industry and manufacturers where it is most vitally needed. The cost, which would be almost prohibitive for a single institution or concern, would impose no appreciable burden upon the wood-using industries if properly distributed. And no matter what the outcome of such investigations may be, the knowledge gained will have a value far exceeding its cost. Delay in acquiring this knowledge can mean only loss.

### Desirability of Introducing Tropical Woods

The American lumber industry should not be antagonistic to tropical woods. Our native woods are not going to be driven off the market. If any American wood goes off the market it will be because the supply fails, and there is no likelihood that the supply of any important timber will fail completely. Before that time comes it will be found worth while to practice forestry, the eventual and only satisfactory solution of any country's timber problem.

An older generation of lumber dealers would be lost in a lumber yard of today. Carpenters and builders in the East are now familiar with Douglas fir, Pondosa pine, Idaho white pine, western spruce, western hemlock, Port Orford cedar, redwood, sugar pine, and other West Coast products, as well as Baltic spruce and other kinds of lumber from the Old World. Much of this change has come about in the last ten years, but in a way it has been going on from the beginning of things. People used first the timber nearest at hand, gradually extending farther afield and discovering unexpected virtues in woods they previously had scorned. Lumber from far-away points has not driven out white pine, northern spruce, southern pine, and cypress—it merely supplements them. It all makes for a new kind of competition, but it is better for the lumber industry that the competition should be between different species of wood than between wood and wood substitutes.

In the case of tropical woods it is better for the lumber trade to accept and become familiar with them and, in fact, welcome them, rather than to fight them and try to keep them out by erecting artificial barriers, such as a protective tariff. Foreign woods can succeed here only when there is a demand for them at a price that will permit a profit to the producer and importer, and such a demand implies dissatisfaction on the part of the buyer with the native material offered him—whether it be price, or quality, or something else. To fight the foreign woods simply because they are foreign is not an act of patriotism and will play directly into the hands of the wood substitutes. Eventually we shall grow most of the timber we need, but so long as we continue to cut it four or five times faster than it grows, it is certainly high time to be looking around for an outside supply to tide us over a strenuous period of readjustment.

The work that is needed to be done has already been carefully outlined. The agencies to do it are available and willing. It remains for those who would profit most from these investigations to furnish the means for carrying them out. Our tropical work at Yale has received no support whatever from the lumber industry. We are constantly appealed to for information and advice, but no funds are ever forthcoming from interested sources to make it possible for us to get the data necessary to answer

the questions asked. The only corporation that is contributing anything is the United Fruit Company. This company is not in the timber business and does not expect any immediate or direct returns from its contributions, but it is interested in anything that promotes the welfare of the countries in which it operates. Our wood-using industries, on the other hand, have a direct and immediate interest in the future supply of their raw materials. In the words of our Chief Forester, "We must find, almost overnight, a fresh source of raw material sufficient to supply 60 or 70 million tons of forest products annually. Instead of a gradual industrial evolution, the change is coming with the suddenness of an economic crisis." Such is the situation. What are we going to do about it?

## Discussion

George P. Ahern.[3] This topic brings up at once the question, "Why such a discussion?" The answer lies largely in the story of the shift of centers of lumber production and the closing down of hundreds of wood-using plants due to lack of local supplies. Many hardwood users are disturbed by rising prices and the difficulty of getting suitable raw material. This situation has impressed the Main Research Committee of the A.S.M.E. sufficiently to authorize a study of the facts and an inquiry into the possibilities of new sources of hardwood supply. Such an inquiry leads inevitably to the present greatest storehouse of hardwoods, the tropics, and the Tropical Plant Research Foundation of Washington was asked by the A.S.M.E. to undertake this work.

As the first step in this investigation a bibliography of tropical woods was prepared and a limited number of copies sent where it was thought they would do the most good. This list included wood experts in some thirty foreign countries. The issue met with a cordial reception. It was accompanied by a letter requesting cooperation in the preparation of a more complete second edition, and much new material was received and incorporated in that edition.

This research project seemed to arouse criticism as to its necessity, as it was claimed there was no shortage of wood supplies and no likelihood of any in the future.

To answer that criticism the writer undertook a survey of the present forest situation in the United States, going over reports and many scientific and commercial journals. The result of this study was incorporated in a paper entitled "Important Factors in Our Forest Problem," which has been submitted to the heads of the U. S. Forest Service and other leading foresters for comment and criticism with the following results.

Dr. A. F. Woods, the Director of Scientific Work for the U. S. Department of Agriculture, in a letter forwarding this paper to E. A. Sherman, Associate Forester of the U. S. Forest Service, stated: "I am sending herewith a very interesting and constructive survey of the forest problem in the United States. It gives a bird's-eye view of the situation and makes it clear that some strenuous work is needed to bring about a more sensible and economic procedure."

Mr. Sherman's reply to Dr. Woods included the following statements: "Major Ahern's statement of the situation is thorough and concise—Major Ahern's manuscript is a logical assembling of facts and opinions. It shows what the situation actually is. Major Ahern's assembled data lead one to the conclusion that the present trend of economic and political forces is heading the lumber industry into ruin both for itself and the natural resources upon which it is based."

Professor Hosmer, head of the Forest School at Cornell, states in a letter of February 4, 1928: "I wish most heartily to thank you for giving us the privilege of seeing this masterly presentation of the basic problem in regard to forests that faces this country. Your report has been read with the greatest interest by the members of this staff. I have taken the liberty of having the report copied in this office in that it contains so much material that is of interest."

A number of other comments of a similar character have been received from other leaders, and no denial of the facts and figures has been made.

As stated in the study referred to, recent reports by foresters in the field all point to a continued rapid disappearance of our remaining privately owned forests, with no check to this decline in sight. As far as our markets are concerned, but two forest regions of importance remain.

The virgin forests of the South are doomed to disappear within ten years at the present rate of cutting. The virgin forests of the Pacific Northwest will disappear or be withdrawn from the market within 20 to 30 years and probably less, as increased demands on this last virgin stand shorten the period.

According to these reports, no serious attempt at better logging practice is evident. Fire protection as a rule is for standing timber and not for cut-over lands. Unregulated slash is the rule, and accounts for many of the destructive fires each year. These reports state that some 60 per cent of the cut-over land is restocking rather unsatisfactorily, and 40 per cent is left practically denuded. Recurring forest fires add annually to the denuded land, and render less productive the remainder of the cut-over land.

The forest-fire situation is disheartening. A few years ago forest fires swept over $7^1/_2$ million acres annually; today the annual acreage fireswept is beyond 24 million.

The annual drain on our forest stock makes a huge total and continues despite depleted capital stock. In 1919 this depletion was estimated at four times the annual growth, a figure which today is much too small.

The national forests, comprising about one-fifth of our total forest area, furnish but three per cent of our wood needs. The farmers' wood lots, some 150 million acres, are mentioned in numerous reports as in decadence and approaching extinction.

Even Colonel Greeley, the head of the U.S. Forest Service, realizes the seriousness of the situation as quoted in the paper: "We must find, almost overnight, a fresh source of raw material sufficient to supply 60 or 70 million tons of forest products annually. Instead of a gradual industrial evolution, the change is coming with the suddenness of an economic crisis."

The most serious phase of this appalling situation is that with these facts well known at federal headquarters no undue alarm is felt over the early disappearance of our virgin timber, deteriorating second growth, destructive logging practice, and rapidly increasing forest fires.

These facts apply to both soft and hard woods. Hence the urgent need for inquiry into new sources of hardwood supply. The story of hickory is typical of what is happening to other valuable hardwoods in this country. In recent years the total drain on hickory has averaged about 400 million board feet annually, and the annual growth is but 84 million feet.

It must be remembered that we use in this country some eight billion board feet of hardwood annually and import but 200 million feet.

We must seek at once new sources of hardwood supply. The only region available for supply in quantity is tropical America. We may need to import within ten years some one to two billion board feet of hardwood. Much scientific research is necessary in the meantime. We must know the location of accessible forest areas, and the stands and distribution of timber; the properties, uses, value and availability of these woods—it

[3] Tropical Forest Research Foundation, Washington, D. C.

takes much time to get the facts—and then the market must be secured.

No country in tropical America is attempting to assemble these facts and seek a market for its timber. As we are the parties most concerned, we in this country must undertake the project of opening up new sources of hardwood supply.

Arthur Koehler.[4] The "overnight" in which we must find a new source of wood supply to which Colonel Greeley metaphorically alludes will not be a short one. But, while many of the wood-using industries are complacently sleeping or working overtime to fill a demand which they stimulated, some one must be putting in a night's work in getting ready to introduce the tropical woods which are to take the place of our diminishing supply of timber.

The introduction of new woods will not be an easy matter. First, the resistance of the wood-using industries themselves must be overcome. Manufacturers of furniture, musical instruments, tool handles, and automobiles will want to be assured that those woods compare favorably with walnut, birch, maple, oak, hickory, and ash, and that they will have no unexpected troubles in putting them through their plants, before they will buy them in carload lots. They also will want to be assured that more of the same kinds will be available for some time to come at practically the same prices. Next the resistance of the consuming public must be overcome. The buyer of furniture made from unknown woods will be suspicious that something cheap or inferior is going to be put over on him. Perhaps the question in furniture is not going to be so much, "How will this wood stand up in service?" as, "Is it the thing to buy?" Hence a public appreciation of the value of new woods must be developed. After the public is once accustomed to buying articles made of tropical woods, marketing difficulties will be largely overcome, provided, as the author points out, that the sale of new species of lumber falls into the hands of efficient promoters.

There need be no fear that the introduction of tropical woods will greatly upset existing lumbering operations. In the first place, because a market must be developed for new kinds of woods, they will come in so gradually that their inroads on markets of native species will not come as a blow to existing organizations. In the second place, indications are that tropical woods cannot be imported any cheaper than the cost at which native timber can be supplied as long as it exists. As native species, especially hardwoods, become depleted, the mill men, as a rule, would not be materially affected by the introduction of new species; in fact, many of them probably would want to get into the work themselves.

There may be some question as to what effect the opening of a new supply of timber in the tropics will have on the growing of a future crop of hardwoods in this country. In this connection it should be remembered that the area for growing hardwoods is greatly limited in the United States. Hardwoods demand fairly good soil, and therefore it is only the more hilly areas and inundated regions that will be used for growing hardwood timber. The more level and drained area will be taken up for raising agricultural crops as the population grows. Hence there is no prospect of an oversupply of native hardwoods, and whatever is grown always will have a decided advantage over tropical woods in the cost of transportation to market.

D. M. Matthews.[5] The author in opening his paper presents a number of questions which will naturally occur to the average individual when the subject of timber from the tropics and its use in this country is broached. Due to unfortunate economic conditions in the lumber industry of this country the average individual does not have the fact of an impending shortage of timber brought to his attention. Prices of timber have, it is true, risen, and risen sharply during the last two decades; but so have the prices of everything else, and only those of us who have been familiar with conditions in the lumber industry know that, in spite of these rising prices, production has been compelled to increase in such a rapid and competitive manner that there has been little profit in the business for the lumberman; and at first glance this would seem to indicate that we had a surplusage of timber in the country rather than any impending shortage. There are only a few of us, relatively speaking, who have had the incentive or the interest to look below the surface and determine the real cause of overproduction of timber in the United States, thereby learning that this overproduction is not a result of existing supplies of more timber than we need but is rather due to the existence of greater investments in the producing end of the lumber industry than current demands justify. It is this overinvestment of capital in lumber production in the country which has turned the industry into a nomadic one, forced concentration in production, and centralized production at the present day in the last big stand of timber in the country in the Pacific Northwest, where the rate of production is so great that although the current needs of the country at large are supplied, the end of the resource is in sight.

The author has fully and adequately answered the questions which he presented at the beginning of his paper. It is very clear that the capital invested in the lumber-production industry of the United States must seek investment in some other line of industry; and that the other industries which are built up largely upon the use of wood as prime raw material must greatly curtail their operations unless some other source of timber supply is to be made available to the country to take up the slack as between the time when our virgin resources are no longer capable of supplying our needs and that time, in the somewhat remote future, when we have put ourselves in a position to supply from our cut-over lands new stands of timber by reforestation. The author ends his discussion with another question, namely, "What are we going to do about it?" He has not attempted to answer this most important question specifically, but the writer is sure that he has very definite ideas as to what we ought to do about it and, indeed, the mere subject of his paper indicates that he is strongly of the opinion that, in this emergency, we should turn to the tropics and direct our energy and ability, as the first lumber-producing and lumber-consuming country of the world, toward the development and utilization of a great storehouse of timber wealth, heretofore largely untouched and, it is to be feared, considered by many of us of little importance or value.

Before proceeding to a somewhat tentative suggestion as to a means of answering his question, "What are we going to do about it?" the writer would like briefly to summarize the underlying facts which arise from a consideration of the paper:

1 There is a present and a still greater impending shortage of timber, and especially hardwoods, within the United States.
2 Prices are rising and substitutes for wood, too often unsatisfactory as regards either price or use, are coming into general utilization.
3 It is necessary to tap new sources of supply.
4 These are to be found in the southern Americas, especially Central America.
5 Woods of value to American industries which can be obtained from these sources are not coming forward in adequate quantities because:

[4] U.S. Forest Products Laboratory, Madison, Wis.

[5] Professor of Forest Management, School of Forestry and Conservation, University of Michigan, Ann Arbor, Mich.

*a* The qualities of these useful woods are imperfectly known;
*b* Existing sources of supply are unreliable and often untrustworthy; and
*c* No reliable data are available as to large potential sources of supply.

If we admit that these facts are incontrovertible we are forced to the conclusion that we must take some steps to make available to the ultimate consumer in the United States the timber which he will no longer be able to obtain from within the United States and which we know to be available elsewhere.

The writer has already said that the average individual is unaware that the country at large is faced with an impending shortage of wood material, and that in the long run this means that he will have to reduce his use of timber and resort to the utilization of timber substitutes often less satisfactory in use and almost always more expensive.

But we cannot expect to turn to the public at large for aid in this emergency except in so far as we can awaken public sentiment in behalf of the conservation of our remaining resources and enlist their support in programs leading to the creation of new forest areas. Nor does the writer think we should expect aid from the public in this direction. The public buys its timber from dealers who make it their business to supply it to them, and the dealers get it in turn from the capital which has become interested in lumber production. It is the interest of these groups which we must enlist if the problem is to be solved. There are four large groups of industry which it seems reasonable to suppose might be interested in the problem. These are:

1 The lumber industry
2 The wood-using industries
3 The manufacturers of milling and woodworking machinery
4 Tropical importers and dealers in hardwoods and timber from the tropics.

When this general subject first came up for consideration by the Wood Industries Division of the Society, the possibilities of obtaining the interest of these four groups were canvassed and it was felt that any attempt toward organization of effort in meeting the problem would naturally most appeal to the wood-using industries and that we could expect greater interest and possible aid from them than from any of the other three groups.

It was apparent right from the start that the lumber industry as a whole was not yet sufficiently educated or sufficiently aware of possibilities for investment in the tropics to look with sympathy upon any movement to develop timber resources in these regions. We expected indifference if not active opposition from the industry, and endeavored to avoid the discouragement of the one and difficulties which would arise from the other by not approaching them. We anticipated that they would answer in the affirmative the third of the author's queries: "If lumber from foreign sources is a potential competitor of the produce of our own sawmills, why not make stronger the barriers of ignorance and prejudice rather than try to break them down?" This expectation would be justified if we attempted to enlist the aid of the lumber industry at the present time. It does not follow that such would be the case ten years from now, when it seems probable that much of the capital so invested will be seeking reinvestment elsewhere. We did think, however, that we could expect the active support of the wood-using industries, but our expectations in this direction were not realized. It was found upon canvassing a large number of firms who were largely dependent upon the use of wood for the conduct of their business that, generally speaking, the wood-using industries felt that if any real effort in time and money was to be exerted in bringing to them new supplies of wood material from the tropics, such effort should be expected only from importers and dealers, and, by inference, from the capital which might invest in the business of producing lumber in the tropics. They generally admitted that they appreciated the problem and would be pleased to be assured of additional supplies of suitable wood material, but most of the individual firms approached did not seem to realize that it might be considered fairly up to them in their own interest to cooperate in the production of such supplies. Only a few firms which were already seeking their raw material from abroad and were therefore importers as well as users seem to be genuinely interested at this time. It must be admitted that this was rather a severe disappointment and a setback to the program we had under consideration. It indicated pretty clearly that more time must elapse and the pinch of shortage of supplies become more evident before active support from the wood-using industries at large could be anticipated. I think that we are safe in assuming that the time is not far distant when the active support of both the lumber-producing and lumber-consuming industries of the country can be obtained. In the meantime it appears to me that the answer to the author's question as to what we are going to do about bringing into the United States and utilizing the timber resources of the tropics lies, in its initial stages, with the tropical-wood importers and dealers and those larger users of high-grade woods who are already reaching out into the tropics to augment the waning supplies of woods suitable for their purposes obtainable within this country. From this group the inquiry which was set on foot a year ago last fall received very real encouragement, and if real cooperation on the part of this group can be obtained, the writer believes the necessary start can be made which will bring about the larger development in the future which the trend of lumber production and consumption in the United States so clearly indicates as an absolute necessity.

We now come to the question of the definite procedure to be adopted in obtaining such cooperation. The work which has already been done has resulted in the formation of a strong committee to consider the problem in all its aspects. It seems to the writer that the next logical step would be an appeal from this committee to selected firms and individuals who may be considered to have an active stake in the cold-blooded business of bringing into this country timbers from the tropics and marketing them at a profit, to form themselves into an association avowedly for the purpose of aiding themselves in placing tropical timber on the markets of the United States and thereby making money out of it. The old axiom that nothing succeeds like success is as true today as it ever was, and if such an association as has been indicated results in the pooling of the interests of the importers, dealers, and such consumers as wish to see an increase in the available supply of hardwoods in the United States, success will inevitably attend their efforts. Such success more than anything else is likely to attract the support and interest of others who would like to share in it.

Raymond J. Hoyle.[6] The paper gives the idea that the solution of the problem of our waning timber supply is to be found in growing more timber or in the importation of foreign woods or both. Not one word has been said about solving this problem of timber shortage by improved utilization of our native timber. Why must we go to other countries for new supplies of wood with all their attendant difficulties while we continue to waste our home material to the extent of from two-ninths or four-ninths of the annual drain upon our forests? Why is it not the best of economy partly to close the spigot of waste rather than import the timber of uncertainty to fill our fountain? This process only delays the day when better economy with our native timber

[6] Department of Forest Utilization, The New York State College of Forestry, Syracuse, N. Y.

must be practiced. Already we have a great number of native commercial woods which are not all at well understood, and which are all in severe competition for markets. Importation of unknown wood will only aggravate this situation.

The author says that lumber from remote points in the United States when brought into old territory in competition with species of long standing has not driven them out but has supplemented the earlier-used woods. In addition to supplementing them it has caused severe competition. Prices on lumber have dropped; there has been great confusion of sizes, grades, and properties of these woods. This great confusion has allowed competing materials to secure many markets which lumber should more properly occupy. What might the situation be if we import foreign woods?

He further says that carpenters and builders in the East are now familiar with our western woods. It is a fact that redwood and red cedar are frequently used interchangeably without a knowledge of the difference. All of our western pines are one grand jumble, and about all that is specifically known is that these woods are some kind of pine. West Coast hemlock, a wood of great merit, is put in a class with eastern hemlock by the public just because it bears the same name—hemlock. Douglas fir is condemned or praised depending on whether soft texture or young-growth material is used for particular purposes, and depending on whether the tree grows on the west slopes of the Cascade Mountains or elsewhere.

As a matter of fact, our knowledge of species in the United States is surprisingly lacking among carpenters, contractors, builders, and woodworkers of every description, and even after centuries of use of some of these woods, our best-trained men cannot answer many questions about wood. What will the importation of unknown tropical woods mean?

We must continue to use our wood rather than curtail its use, for this latter condition would not result in fo. st perpetuation. Use creates value and encourages timber growing. About four-fifths of our timber land is privately owned, and the growing of timber on this area cannot be expected until closer utilization is practiced. This problem of closer utilization is linked up closely with the economic problem of overproduction. Overproduction and competition are the causes of present-day low timber prices, and low lumber prices are not conducive to close utilization.

In conclusion, while the growing of timber is essential and desirable for our future needs, this practice is dependent on the solution of our economic and close-utilization problems. Imports of foreign woods in any appreciable amount will complicate our situation and delay the day when forest growth and use are on a more stable basis.

H. M. Curran.[7] We have more hardwood timber than our industry demands. Because of overcutting, the lumber industry is in as bad a way financially as the farmer. Price levels are high and quality low because we have pushed exploitation into the more inaccessible regions or used low-quality trees or small-sized trees left from earlier logging.

High-grade, medium-priced hardwoods must come from new virgin forests.

The strong point made by the author, namely, that we must in the near future find large supplies of wood of high quality if wood substitutes are not to drive our own well-known species from the market, is a telling argument to silence the opposition of those who fear the entrance of new hardwoods.

While the author's experience is less extensive as to field conditions than that of many of the tropical foresters, his intimate knowledge of the woods themselves is greater than of any person known by the writer today. When he states that these woods of the tropics have the qualities to supplement our own waning supplies, it may be taken as the expression of one who has weighed carefully all the existing evidence, and knows he is safe in the statement.

[7] State Forester, North Carolina Department of Agriculture, Raleigh, N. C.

H. P. Brown.[8] The accuracy of the statistics quoted by the author from Colonel Greeley's paper in the *Economic Geography* is unquestionable. Our available timber resources have been carefully inventoried, and, at the present rate of consumption, it is only a question of time before increasing scarcity will react seriously as an economic brake upon our future industrial development. Unfortunately some of the pioneers in the forest-conservation movement underestimated the timber still available and prophesied the lean years as coming too soon, and this has served to lull certain interests into a sense of security. The theoretical date of the complete exhaustion of our timber supply at the present rate of consumption has been pushed farther into the future, but leaner years in lumber production are as certain as death and taxes.

In a discussion of the possible utilization of tropical woods, it is well to bear in mind certain fundamental aspects of the question. We are utilizing our timber several times faster than we are growing it. Our reserve supply of soft or coniferous wood is proportionately much greater than our hardwood supply. Coniferous trees are trees essentially of the temperate zones; while they occur in tropical forests, the supply of coniferous timber is negligible. Conifers should be grown in the temperate zone, and it is most economical to grow them there. There is no reason why, using proper forestry methods, we should not grow, in the confines of the United States, all the softwood lumber that we require.

In the writer's opinion, once the original stands of our hardwoods are exhausted we shall never be able to grow them in sufficient quantity to meet our requirements. Hardwood trees attain their best development in the tropics, and it is here they show the best annual increment growth, speaking in terms of averages. Just as the dark races are the result of a tropical climate, working through generations, so are hardwood trees the result of tropical conditions. On the other hand, the white races belong to the temperate zones; so do the conifers.

Granting that we cannot hope ever to grow hardwood lumber in sufficient quantity for our needs in the United States, the question of tropical hardwoods comes to the fore; the demand for tropical woods is here to stay. Their utilization involves finding means of identification, the study of their technical properties in the laboratory to determine their proper uses, and investigations in the field to determine if sufficient supplies are available to warrant marketing at home. To do all this requires funds. No federal or state funds have been made available to date, and there is little likelihood of this possibility in the near future. But two of the forestry schools, Yale through the efforts of Professor Samuel J. Record, and the New York State College of Forestry at Syracuse through the writer's, have devoted any attention to tropical timbers, and this has been largely due to their enthusiasm on limited funds and in the writer's case to what is even more important, limited time owing to teaching responsibilities. Certain firms of importers have been shrewd enough to compile much information upon the timbers of districts in which they are financially interested, and in some cases at least they have employed scouts with experience in tropical forestry to make surveys for them. The lumber industry at large cannot expect to obtain much information from this source, however, as it is usually considered as con-

[8] Professor of Wood Technology, The New York State College of Forestry, Syracuse University, Syracuse, N. Y.

fidential, to be used for the advancement of their own monetary interests.

The writer would urge that the lumber industry set aside funds for the study of tropical timbers, not only of our American tropics but of those of the Old World as well. American capital is seeking outlets throughout the world. Foreign bonds at present are more attractive than domestic, and the American people are rapidly acquiring investments in the tropics. The study of tropical timbers should proceed as we acquire a better knowledge of the torrid zone.

The information upon tropical timbers should be made available to the whole lumber industry, not to the small coterie which is interested at present. The demand for tropical woods will increase mightily in the next decade, and the lumber industry at large should profit financially. Divide up the profits among you; there are enough for all.

Funds made available for the study of tropical woods, in the writer's opinion, should not be allocated to one school. A healthy competition in research between schools is desirable. Research fellowships of a thousand dollars a year would help materially in forwarding the study of tropical timbers. Men would thus be made available to carry on the work under proper direction, and they at the same time would receive a training which should render them valuable to firms engaged in the importation of tropical timbers. Not only for tropical timbers but for domestic timbers as well, the lumber industry can well afford to finance fellowships which will enable it to get men who are better trained in the structure and the physical, including the mechanical, and chemical properties of wood. The lumber industry, whether it be domestic or tropical woods, is competing with steel and concrete. The forestry schools are sending out their best men, but they are often outclassed for lack of training, for lack of understanding of raw-product wood. Agents must know "wood" to compete with steel and concrete engineers. The National Lumber Manufacturers Association is now engaged in a mammoth advertising campaign. How much more drive, how much more impetus, would be secured with properly trained men. The men now in the work are able, but blind men cannot fight. Four years at a forestry school is not enough. Scholarships are needed for additional years, and this applies for domestic woods and for tropical woods alike.

C. D. Mell.[9] The author asks five questions in the first paragraph. The writer's answer to the first two is, "None whatever." The third is not entirely clear. The last two questions he would answer most appropriately by the Latin-American slang "Quien sabe," meaning "Who knows."

Apparently, the object of the paper is to obtain contributions from organized business and scientific men so as to enable the author to send his students to tropical America to collect wood samples. He states that the United Fruit Company—not in the lumber business—is the only organized unit that is making funds available for enlarging his activities, implying that the wood industries are lacking in vision in not contributing to his project.

Moreover, the title of the paper, "Our Need for Knowledge of Tropical Timbers" apparently has reference only to tropical American timbers, as nothing is said regarding woods from the Philippines, for instance, which are tropical and which are now entering this market in rapidly increasing quantities. It is well known that the woods occur in undeniably large quantities in the Philippines, which are among our insular possessions, and can furnish us with the necessary supplies, when "we must find almost over night," borrowing Mr. Greeley's text, "fresh sources of raw material sufficient to supply 60 to 70 million tons of forest products annually."

The Philippine mahoganies, for instance, can come to our rescue and satisfy the author's final question, "What are we going to do about it?" At the hearings of the Federal Trade Commission, when the question of nomenclature was under review and notwithstanding the fact that there are over 30,000,000 feet of these woods now being used in this country and that all the users are satisfied, the author made statements which, if they could not be controverted, would greatly lessen the use of these very admirable woods in this country; their use was established at tremendous expense and hard work on the part of dealers, but the author asks for funds with which to seek other woods in foreign countries after he has discouraged the use of those that have been found available in our insular possession.

It is safe to say that no one who is measurably acquainted with the lumber business or with some phases of the wood industry and their relations to the supply and demand of lumber will be alarmed by the statements of Mr. Greeley and the author. They appear to be unaware of the frequent recurrence of predictions of a complete exhaustion of our domestic lumber supply. More than 150 years ago a fear of a timber famine was in the minds of many in America, and it was suggested that the only means of averting a serious economic crisis was to plant catalpa trees on all available lands not needed for agriculture; the catalpa tree is a fast grower, but it remains too small to produce lumber logs.

Our period obeys the same process, and the author's proposal is in line with the catalpa plantation scheme. Since the early timber famine reports, the lumber industry continued to prosper; it survived and assumed increasing proportions, and even now the common complaint is among wholesalers that the demand is poor and that selling their mills' output is getting more difficult. The lumber substitutes are rapidly gaining ground, and we now read accounts of the fact that the lumber industry is spending two million dollars annually in an advertising scheme designed to discourage the use of the lumber substitutes.

If the author should succeed in finding the woods he imagines are somewhere in tropical America, the lumber industry would probably have to spend another two million dollars annually in order to discourage the use of foreign woods and to enable the mill owners here to sell their domestic lumber in the home markets.

The author takes it for granted that his scouts will find an abundance of good timber the wood-using industries can use, but apparently he has no first-hand knowledge of the tropical bush and does not realize that the American tropics outside of limited areas in southern Mexico and perhaps parts of British Guiana are almost depleted of timber. Dr. John Gifford, the father of American forestry, once said that there is a lot of wood in tropical America, but that very little can ever be used here; he also stated that if we want just *wood*, we have plenty right here in the United States.

In the foregoing the writer has endeavored to point out reasons why the lumbermen and woodworking concerns can have no faith and little or no collective interest in helping defray expenses incident to searching for woods in tropical America. The republics to the south of us import from the United States the bulk of the structural timbers as well as the common lumber they use. These countries cannot furnish their lumber requirements from their own forests; therefore it is inconceivable to believe that the author could find enough of available material not only to satisfy the local needs, but also to ward off Mr. Greeley's predicted economic crisis in the United States.

# Problems of Design for Mass Production in The Furniture Industry

## An Application of the Line Method of Assembly to the Manufacture of Office Desks

By BAYARD EDWIN RICHARDSON,[1] GRAND RAPIDS, MICH.

WHILE the title of this paper is broad enough to encompass the furniture industry as a whole, it is not the purpose or intention of the writer to set forth the full possibilities of design for mass production in every branch of the woodworking industry. Such an undertaking would require the combined efforts of many men selected from diversified branches of the industry, and their combined knowledge, properly compiled, would more fittingly embrace the entire thought expressed in the title.

The subject of this discussion will be confined more particularly to the problems of design for mass production in the manufacture of commercial furniture. While the principles involved are now in general use in the automotive industry, the application of these principles to the manufacture of office desks will disclose a new departure in this branch of the furniture industry.

All previous conceptions of structural design have been abandoned, and while external appearance has been only slightly altered, the component parts of the desk have been radically changed.

These changes in structural design have brought about marked reductions in manufacturing costs, greater strength in the assembled products, and best of all, a method of assembly which permits the use of the principles of mass production now so successfully used in the automotive industry.

### Line Production

Modern industry is indebted to the automobile for the principle of line production, and production engineering has without doubt achieved more through the automobile industry than through any other industrial development. But the application of these principles to the manufacture of furniture has been slow. It is surprising and almost unbelievable that an industry which has been in existence for centuries should be so slow to take advantage of the production methods developed by and universally used in this much younger industry.

Surely the furniture plants can boast of marked improvements in their manufacturing processes—for marked changes in plant management and machinery methods have come to light in recent years in every branch of the wood-working industry. It would not be fair to say that the automobile industries have a monopoly on all of the engineering brains of the country for there are many shining examples of accomplishment in the direction of production engineering in a number of the larger woodworking plants of Grand Rapids and other cities having similar industrial plants. Nevertheless tne fact still remains that none of these has, as yet, taken full advantage of the principle of line production. Just why should this condition prevail in our industry?

A careful analysis of the problem of line production as applied to our particular product has brought to light many interesting facts regarding structural design for large production. It has given us a better understanding of the relationship of these two factors, which play such an important part in the manufacture of any product.

### Production by the Conveyor System

It has been demonstrated conclusively by all of the large automobile plants in this country that by means of a production line, it is possible to carry on assembly operations at a predetermined rate of speed; operators must keep up; materials must flow to the assembly line; the finished product must drop from the end of the line at scheduled intervals; and lowered costs are bound to result from such a program.

The mechanical conveyor has become the backbone of the materials-handling system. Materials must be handled with greater dispatch and less demand on floor space. The conveyor must be kept moving. Various types of power-driven conveyors have been developed to meet these demands.

Electric screwdrivers and socket wrenches have been in the course of development for many years and within the last two or three years have supplanted laborious hand methods, particularly in line-assembly operations.

All production is a matter of time. It is the basic factor in every production schedule. Time and speed are synonymous, because change of speed means a corresponding change in production time. Speed flexibility is therefore vital. To be able to change the time production of any machine it must be flexible in speed. There is one best speed for every operation.

The day's production and the number of men on the line determine the speed of the assembly conveyor. Variation of quantity per unit of time or in the number of operators at work calls for an adjustment in speed of the assembly conveyor.

All production machinery must be flexible.

In order to take full advantage of the power-driven assembly conveyor, it is necessary to have all parts entering into the assembly completely processed from raw material to a state of completion before being fed to the assembly line.

A high degree of accuracy must be adhered to in the production of parts, to insure quick assembly.

In the use of sub-assembly operations the number of operations carried out on each unit is reduced to the minimum, at the same time quantity production is at a maximum. This plan shortens the final assembly operations, and permits the use of a shorter assembly conveyor, with fewer men to maintain a desired production schedule.

At each operator's station along the assembly conveyor are the tools necessary for his particular part of the work. As the conveyor passes along, each operator contributes his share of the work. The separate parts which enter into the assembly are brought to the line at proper intervals. This insures constant flow of materials.

### Changes in Construction of Desks

To apply these principles to the manufacture of any product requires a large volume of sales. Without large volume of sales no real production schedule can be entertained. The economies resulting from mass production depend primarily on quantity. The larger the quantity, the greater are the economies to be made.

The sales possibilities in the commercial-desk field are very great. It goes without saying, however, that sales will invariably increase with every decrease in retail price. This

[1] Plant Engineer, Stow-Davis Furniture Co.

Presented at the First National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., October 17 and 18, 1927.

has been the impelling thought back of our efforts in attempting to apply the latest principles of mass production to our product.

Early attempts to fit any of our desks, as they were then being built, into the production picture just painted, disclosed the fact that the construction was all wrong. The construction of our desks, like all other pieces of furniture, had been developed to fit the age-old art of cabinet making. It required the skill of a cabinet maker to assemble our product. To dissect that art for distribution along an assembly line meant the teaching of many new tricks.

This procedure was useless because only minor economies could be gained. It still remained that the total number of operations were practically the same, whether done at the cabinet maker's bench or on the assembly line.

Thus it became evident that some new construction, some new way of putting wood together, would have to be developed to permit the use of line-production principles; a construction which would eliminate the cabinet work, the hand-fitting and gluing operations now in common use in all furniture plants.

Every known method of detail construction used in the furniture industry was given careful consideration in an effort to determine a suitable means of applying the principle of line production to the manufacture of desks. We were determined to effect the greatest possible savings in machining operations, as well as in the final process of assembly.

None of the present woodworking methods of construction seemed to fit all of the requirements named, so they were all laid aside and forgotten completely for the time being while a search for new ideas in construction went forward.

### Combination Wood and Steel Construction Adopted

Careful consideration of automobile-body construction disclosed the fact that steel and wood can be combined advantageously, and this thought served to direct our efforts in working out a new construction.

Considering for a moment the general details of any commercial desk, it will be apparent that they are all built along one conventional line, and are very similar in general appearance. Compared to the finer types of executive office furniture, the average commercial desk is severely plain and lacking in beauty. All have plain square corner posts, plain end and back panels, square-edged tops, and drawer fronts lacking any trace of ornamentation other than some cheap type of wood or metal pull. The corner posts usually terminate at the floor with a brass cup or socket.

To develop a new type of construction for desks without improving the general appearance to a marked degree, would be falling short of the desired goal. From the sales standpoint alone a marked improvement in exterior design over the general run of commercial desks would be an advantage.

With all of these facts directing our efforts, a new desk construction gradually developed, having an interior framework of steel and an exterior of wood—assembled without the use of glue and without the skill of a cabinet maker.

### Structural Details of the New Desk

Square corner posts were abandoned, giving way to rounded corners formed by laying up the end panels of the desk in specially built cauls which bend the five-ply veneer to the desired shape at the ends, at the time of applying pressure. This eliminated the solid wood used for corner posts, and all the machining operations necessary to attach the end panels to them. These new panels are used both on the ends of the desk and in the well space, two panels being used to form the sides of each pedestal of the desk.

Top and bottom pedestal frames or plates are formed of steel, having grooves pressed into them to receive the end panels, while inside of this assembly is located the steel frame formed of angles spot-welded together in such a manner as to provide slides for supporting the pedestal drawers.

At the corners and on the under side of the bottom pedestal frame are steel cups spot-welded in place which receive the upper ends of the turned wood legs of the desk. These turnings are bored to permit a bolt to pass up through their center, and are provided with a pressed-bronze cup at the floor line. The bolts referred to pass up through the legs, base frames, and top frames of each pedestal and serve to clamp the complete pedestal assembly rigidly together. A small back panel closes the back of each pedestal and is securely clamped in position between the top and bottom frames along with the end panels.

Between two such pedestals is located the well-drawer frame which is also fabricated of steel. This is secured to the end panels of each pedestal by means of bolts. The five-ply desk top is secured to this completed assembly by means of wood screws which pass through holes punched in the top pedestal frames.

All steel parts making up the inner frame of the desk pedestals are stamped from cold-rolled steel, and when spot-welded together make a rigid assembly, resembling in appearance the familiar steel structure of the modern skyscraper.

The drawers used are made of wood, with the conventional dovetail construction at the corners and three-ply veneer bottom panels completely framed in. These are assembled in a specially designed air clamp, which insures uniform pressure at all dovetail joints and perfectly squares the work at one operation.

All machining operations on the wood parts entering into the new desk are being done with particular attention to accuracy in dimensions, on production machines of the very latest type, steel snap gages being used for checking each set-up.

Careful attention was given to the design for interchangeability of both the steel and wood parts entering into the construction of the various sizes of desks.

It will be apparent from the description given that the completely assembled desk, from the exterior viewpoint, is primarily an all-wood desk, having an interior superstructure of steel, greater in strength than that of wood.

Only the base molding and the narrow beads between the drawers in each pedestal are exposed steel. These surfaces receive a natural wood-grain finish before reaching the final assembly line, and match the finish of the wood perfectly.

### The Finishing Room

One great advantage of the new construction lies in the fact that the component parts can all be put through the finishing room before proceeding to the assembly line. This feature led to the use of a mechanical conveyor for the finishing of all parts.

The conveyor is of the roller-chain type having wood slats which form a continuously moving table 24 in. wide and 50 ft. long—passing through the spray booth and ventilated drying tunnel, from which it emerges sufficiently to permit unloading.

A variable-speed drive provides adjustment of travel to meet every requirement. This system of finishing reduces the problem of spraying lacquer down to the terms of square feet of surface covered per minute of time. It insures a uniform coverage on all surfaces which pass before the operator stationed within the spray booth.

The drying tunnel carries off the fumes which are emitted from the wet lacquer surface in the drying process. Temperature and humidity control, together with a constant change of air in the tunnel, insures a uniform drying rate for the finish and eliminates the element of chance in the finishing room.

These ideal conditions hasten the drying process so that all parts can be readily handled when discharged from the end of the conveyor, where they are placed in portable racks and allowed to stand a suitable length of time before being rubbed.

Portable racks serve to carry the finished parts to the stock-room which is parallel to and on both sides of the assembly conveyor. This arrangement supplies every operator on the assembly line with the correct parts to carry on his part of the construction process.

### Advantages of Line-Assembly Method

A power-driven mechanical conveyor similar in construction to that used in the finishing room, and approximately of the same length, serves the process of assembly. This is also provided with a variable-speed drive, permitting a variation of from 1 to 3 ft. per min. to meet variations in the production schedule.

One of the great advantages of this entire process of line production lies in the fact that orders received in the morning's mail can be delivered from the assembly line to the packing room for shipment by noon of the same day. This is a condition never before attained in the furniture industry. It is one of the most important developments resulting from our study of structural design for mass production.

From the standpoint of exterior design, the new construction lends itself readily to modification in detail. Drawer fronts can be overlaid with fancy woods, or shaped on the face. They can be made flush front, without bar rails between each drawer. Different turnings can be used to fit any period in design for the legs of the desk, and fancy woods may be applied to end panels, back panels, and top. Character changes in the base molding are aso permissible without affecting materially the interchangeability of structural parts. Thus a number of patterns differing in external design can be assembled at will from the stock racks carrying the finished parts.

A more desirable manufacturing schedule than this could hardly be hoped for.

### Economies Resulting From New Construction

Before bringing this paper to a close, it might be well to point out some of the manufacturing economies resulting from the new construction.

First of all, a marked saving in materials and labor can be realized from the substitution of steel for wood in building the framework.

Greater accuracy can be maintained, thus eliminating all hand-fitting operations at the time of assembly.

All gluing and clamping operations have been discarded for a much quicker form of assembly, which can be done by unskilled labor in minutes, as compared to hours for cabinet making.

Finishing costs have been lowered considerably as a result of the continuous flow of parts through the spray booth as against the method of finishing a fully assembled article.

The total number of machining operations on all wood parts has been reduced. Those remaining have been simplified to fit into only the faster cutting operations performed by the latest types of wood-working machinery.

Many smaller savings have resulted from quicker processes of handling materials in various departments by methods which have been omitted in this article for the sake of brevity.

In conclusion, it is hoped that this new development in the manufacture of commercial furniture will point out more clearly the relationship of structural design for mass production in other branches of the woodworking industry and the fact that the old order of things can be departed from in this day and age of competition.

New methods of construction must be developed before line production and assembly principles can be fully applied to the manufacture of furniture.

## Discussion

The Author, in answer to many questions, brought out the following points: The upper frame of the desk is of steel, and has a projecting lip around the upper part of the pedestal, through which ordinary wood screws pass up into the top to fasten it in place. The five-ply top referred to is of conventional construction, heavy core stock with cross-pinning on both sides and face veneer. The desk is to be put on the market in two grades, one a commercial grade and the other lending itself more particularly to use in executive offices. There will be a $1^1/_4$-in. top on the commercial grade and a $1^1/_2$-in. top on the better grade.

The rate of speed of the conveyor through the spray booth is adjusted to give the proper coverage on unit of area, in unit of time, we will say. The operator covers the surface as it goes by and there is very little lost motion. We find that the rubbing operations are done in much less time if the parts are accessible than when finishing the completed desk. A desk is a large, bulky piece of furniture and must be handled; there are many angles and corners to get into, and curved surfaces and inaccessible places that take time. We are now finishing all separate parts as they pass long. Each man does his operation as it moves along.

No attempt has been made to measure the quantity of lacquer used. In fact many things referred to in the paper are only just emerging from the stage of experimentation. It will be noticed that no reference has been made to any exact detailed savings. It is hoped that figures will be available soon which will prove a number of the broad claims made here.

It is going to take about five minutes with the combined efforts of a number of men, to completely assemble one of the desks from the start to the finish.

We have tried to retain the beauty of wood desks by making the entire exterior, so far as construction permitted, of wood, and using steel only in the interior for such parts as are better made of steel. The minimum of steel shows on the face of the desk. I do not think we have sacrificed anything in appearance by the use of steel. Through actual tests, we find the sample desks turned out are far superior in strength to desks made as well as it is possible to make them entirely of wood.

# Compressive Tests of Balsa Wood

By A. H. Stang,[1] Washington, D. C.

BALSA wood has been used on several occasions to insulate machinery so that the vibrations would not be transmitted to the floor, and has apparently proved successful for this purpose. Since few data are available on the compressive properties of balsa wood, the United States Bureau of Standards conducted tests to determine how much shortening took place under a uniformly distributed load, how much permanent set remained when the load was removed, and the compression-time relations when the balsa wood was loaded by dead weights.

Eleven specimens furnished by the Balsa Wood Company, New York City, each 12 × 12 in., were used for these tests. Each specimen was composed of three boards, side by side and dovetailed together. Three were one inch thick, five were two inches thick, and three were three inches thick. Three of the specimens had been coated with a black paint which appeared to be a bituminous compound. These specimens will be referred to as painted, the others as unpainted.

Nine of the specimens were tested in compression by applying the load to the 12 × 12-in. faces through a large spherical bearing attached to the moving head of the testing machine.

The decrease in the thickness of each specimen under load was measured at the middle of each of the four sides by dial micrometers which were graduated in thousandths of an inch. An initial load of 10 lb. per sq. in. was applied, then the load was increased by increments of 10 lb. per sq. in. until the proportional limit had been exceeded. After each increment, the load was decreased to the initial point.

The deformations of the specimen were read at each load.

The set due to a given load was taken as the difference between the readings at the initial load after the given load and the first readings taken at this initial load.

At low loads the proportionality between the stress and the shortening of these specimens was remarkably close. It was therefore possible to find fairly definite values of the proportional limit from the stress-strain curves.

For stresses higher than the proportional limit, the compression increased more rapidly than the load, and consequently the load increments were increased and the tests were continued until the final thickness was about one-half of the original thickness.

Typical curves are shown in Fig. 1 for specimens of each of the three thicknesses. The proportional limits and moduli of elasticity together with the weights of the specimens are given in Table 1.

The specimens three inches thick were composed of pieces which contained the heart of the tree. These specimens had a lower density than the specimens one and two inches thick which did not contain heartwood. The tests showed that they also had lower proportional limits.

Lower values for the modulus of elasticity were found for the painted than for the unpainted specimens. They also had a higher density.

None of the specimens was perfectly elastic. The set after each application of load was in all cases a very appreciable part of the deformation under load and was, roughly, one-half of this deformation up to the proportional limit.

At higher loads the set became proportionally larger.

As with specimens of other materials having a large area compared to thickness, the balsa wood did not appear to have a definite maximum compressive strength. The load continued to increase as the thickness decreased.

A study of the test results of these nine specimens seemed to indicate that the density of the wood was an important factor in the strength properties of the material. For use as supports under heavy machinery, the different supports should have the same properties to preserve the level of the machine. Two other specimens, 2-D and 2-E, each two inches thick, were therefore prepared. Each specimen consisted of three boards joined to make the 12 × 12-in. surface, and these parts were selected so that both specimens had the same weight, as given in Table 1.

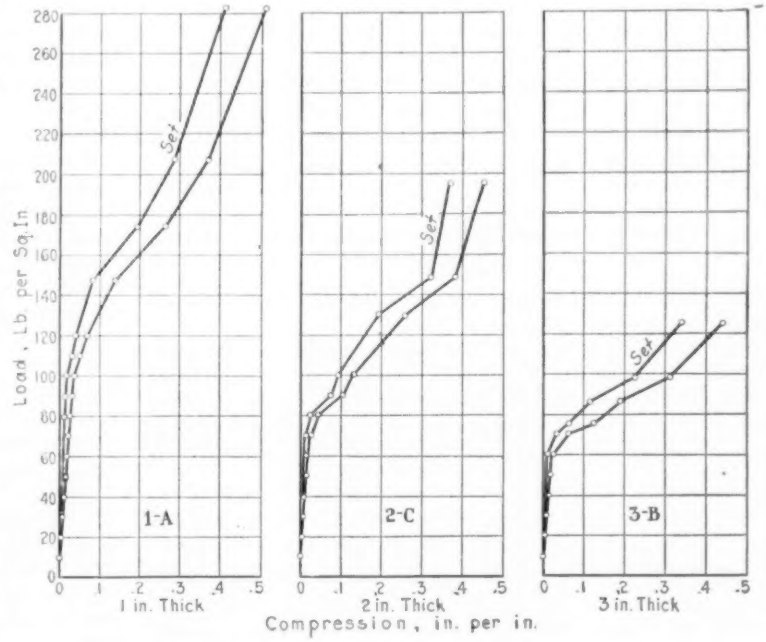

Fig. 1 Stress-Strain and Stress-Set Curves

TABLE 1 PROPERTIES OF BALSA WOOD SPECIMENS

| Specimen No. | Condition | Thickness, in. | Weight, lb. per cu. ft. | P-limit, lb. per sq. in. | Modulus of elasticity, lb. per sq. in. |
|---|---|---|---|---|---|
| (Tested in a testing machine) | | | | | |
| 1-A | unpainted | 1 | 7.76 | 85 | 2550 |

[1] Engineer, Bureau of Standards, Washington, D. C.

Presented at the First National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., October 17 and 18, 1927, and published by permission of the Director, U. S. Bureau of Standards.

Each of these specimens was tested under a deadweight of 15,000 lb. which was applied to the 12 × 12-in. face, thus producing a compressive stress of 104 lb. per sq. in. Vertical compressometers were mounted at the center of each of the four sides of the specimen to indicate the shortening produced by the load. They were subjected to this load for about seven days, readings being taken as indicated in Fig. 2, which shows the time-compression curves. The rate of compression for these two specimens, which had the same density, was practically the

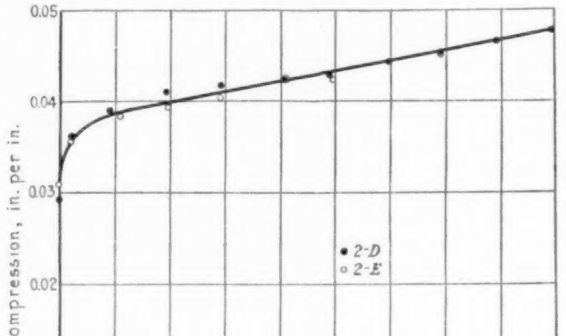

FIG. 2 COMPRESSION-TIME CURVES UNDER DEAD LOAD OF 104 LB. PER SQ. IN.

same for both specimens and was about the same on the seventh day as it was on the third day.

With material of this kind used for the support and insulation of heavy machinery that is under a constant load, it is probable that a stress about equal to the proportional limit can be safely used. Careful selection based on uniform density of relatively heavy balsa-wood blocks appears to be well worth while for this purpose.

## Discussion

W. J. KREFELD.[2] The test results given by the author indicate a variation of the proportional limit as determined by a static test from 48 to 95 lb. per sq. in. with a change in density from 5.67 to 7.68 lb. per cu. ft. This fact is of considerable importance in the use of the material as a support under heavy machinery, as has been suggested by the author, especially where the area is large, necessitating the use of a number of pieces suitably connected together. A variation such as just indicated over a large supporting area would undoubtedly result in a non-uniform bearing pressure, with probable overload of the denser material and unequal settlement of the machine.

The curve shown in Fig. 2 indicates practically a uniform rate of compressive strain under a constant static load over a period of 1 to 9 days. It is to be noted that these specimens were of comparatively small area when considering machinery supports, and no data are available concerning this rate of compressibility for wood of varying density. The average compressibility of a large area of a composite foundation bed would depend upon the relative properties of the wood used in making up the bed. Where the supporting bed is of uniform material, Fig. 2 would indicate a continued settlement and, while the machine may remain level, its alignment or grade would be changed, which would be of considerable importance in the case of shafting, bearings, etc.

All of the tests have been made under static loads. It would be interesting to determine the properties with respect to the compressibility-time relation under repeated loads, introducing the effect of vibration and impact produced in many machines with moving parts. It has been the experience in other species of wood that the resilience may ultimately be destroyed when loads slightly above the elastic range have been applied repeatedly. In order to determine the permanent supporting power of balsa wood under a vibrating machine it would be necessary to ascertain the limiting stress under which practically no further permanent sets were produced.

The writer would suggest that the author furnish data relative to the ultimate deformation under varying static and dynamic loads.

[2] Engineer of Tests, Columbia University, New York, N. Y.

H. F. HOEVEL.[3] The most important requirements of a good insulating material against the transmission of vibration of machines are permanent and sufficient elasticity. Its task is to absorb vibration by converting the energy of motion (kinetic energy) into internal strain (latent energy). An insulating material will answer these requirements all the better the more it compresses or shortens under a certain load, and the more completely and quickly it recovers and resumes its original shape after the load has been removed.

Machines, including their foundations, placed on insulating material usually exert a pressure on the material of up to 2000 lb. per sq. ft. and very rarely up to 3000 lb. per sq. ft. A material must be judged by its elasticity and insulating effect within these loads.

From the data given in Fig. 1 it appears that balsa wood compresses very little and therefore has little insulating effect under loads up to 20 lb. per sq. in., or the equivalent of 2880 lb. per sq. ft. Attention is also drawn to the statement in the report that the set after each application of load was in all cases a very appreciable part of the deformation under load and was roughly one-half of this deformation up to the proportional limit. This means that balsa wood after a downwardly directed vibration impact will recover only one-half of its compression. Consequently the energy of motion of additional downwardly directed vibration impacts will not fully be converted into internal strain by balsa wood but will pass through the insulating material and will travel into the soil as vibration. The elasticity and resilience necessary for the insulation of machines has been attained to a remarkable degree in the product known commercially as "Korfund," through the peculiar type of construction employed. It consists of strips or blocks of pure natural cork, specially selected for this purpose, carefully cut to size and bound together with an iron frame which is not quite as thick vertically as the cork. The cork used is treated by a special process to preserve the normal degree of moisture which is so vital to it.

Tests made by New York University, College of Engineering, show that it compresses readily under a pressure of about 2000 lb. per sq. ft. and that the permanent set immediately after the load has been removed is only about $1^1/_2$ per cent to 4 per cent, and even less, 5 minutes after the load has been removed.

PAUL H. BILHUBER.[4] The writer's first knowledge of the use of this wood as a packing material was its application by the Victor Talking Machine Company of small blocks glued to the insides of the cases into which machines were packed, the idea

[3] President, Korfund Co., New York, N. Y. Mem. A.S.M.E.

[4] Assistant Factory Manager, Steinway & Sons, Long Island City, N. Y. Assoc. A.S.M.E.

being that they would take a certain amount of compression, be more or less elastic, and protect the contents of the case from the shocks incident to transportation. That practice apparently was given up in favor of some more elastic material after about two years. Steinway & Sons also made similar use of it for a very short time. It seemed that when the material was compressed and dented, it did not have the elasticity the users hoped to find, and for that reason its usefulness ended. The balsa tree is of very rapid growth, therefore the texture of the wood is not uniform; it is very hard to get large pieces of uniform texture.

T. D. Perry.[5] The writer had quite an acquaintance with balsa wood just before the World War, and one of the great difficulties encountered at that time was its very great tendency to decay. It is a very soft wood, very porous, and absorbs moisture readily. The wood decays so rapidly that it has been found necessary for various applications to impregnate it with paraffin. In attempts to make the wood strong it has been compressed after impregnation, and the author has seen pieces of it compressed almost to the hardness of oak. Balsa wood did not seem to get very far then as a wood of commerce. The writer's last contact with it was in connection with life preservers. It has almost twice the buoyancy of cork, and with the paraffin impregnation has a long life. Many of the life rafts observed toward the end of the war, instead of being blown up with air or filled with pulverized cork, were made of solid pieces of this wood. The wood is so soft that one may with perfect ease drive a half-inch dowel into a block without fear of splitting or in any way damaging the wood. The writer has grave doubts as to its value as a cushion for machinery in comparison with the harder woods we are accustomed to using. Pines, spruces, and birch woods, and a number of native woods would have nearly as much elasticity as balsa wood under compression and would be easier to get and not so liable to deteriorate.

Arthur Koehler.[6] There seems to be no mention of the moisture content of the samples tested. That is very important because of its great influence on strength. A piece of spruce, for example, kiln-dried, may be four times as strong as the green wood. Anything put into machinery would be subject to high variation in this respect; in one shop it might be air dry and in another shop it would have a very high moisture content down on the floor, thereby greatly reducing the strength.

At one point in the paper the "heart of the tree" is mentioned. In the next sentence the words "specimens for lower density which generally contain heartwood" appear. Now, in all the pieces of balsa that the writer has seen there seemed to be no difference between heartwood and sapwood. They were all the same color and were uniform throughout. Perhaps the author will explain in more detail just what he means, and if he means a certain distance from the bark.

C. H. Tanger.[7] Experiments have been conducted on balsa wood as a vibration absorber underneath household refrigeration units. In order to get the proper characteristics of the wood balsa was used as a core for a laminated board, a board hard of surface being employed to distribute the weight over a large surface. The balsa-wood core was subjected to a specific-gravity test for density before laminating.

[5] Director, Woodworking Division, Bigelow Kent, Willard & Co., Inc., Boston, Mass. Mem. A.S.M.E.

[6] Forest Products Laboratory, Madison, Wis.

[7] Kelvinator Corporation, Detroit, Mich.

The refrigerator manufacturers are particularly interested in its use as an insulator. Because of its strength, a separate frame for the refrigerator is not required; the insulation and the frame are one.

C. C. Travis.[8] Balsa wood is being used with considerable success in the aircraft industry at this time, and its ability to absorb vibration and reduce noise, as well as insulate against low temperatures, would seem to indicate that this field promises much for this tropical wood. It has also found favor as a material for the manufacture of radio parts, because of its excellent acoustic properties. Another interesting use of balsa is in the construction of the new ramp alongside the Grand Central Station in New York City. The city engineers found that a layer of balsa under the pavement absorbed a large part of the vibrations that ordinarily would be transmitted into the steelwork. It is also being used as a sound deadener where a vessel is inclined to vibrate sympathetically with a machine. Oil burners have been made to operate quietly by placing them on balsa-wood bases. Its use in household refrigerating machines has already been mentioned.

The density of the wood can be controlled by proper attention at the point of origin. Balsa trees reach commercial size in six to seven years, when they attain a diameter of 22 inches and reach a height of 50 feet. At that stage the wood contains about three times its weight in water. After that time the sap starts to harden and the wood deteriorates at an increasing rate. Prior to two years ago the chief difficulty lay in this fact. In other words, the wood was cut after it had reached too advanced an age, after the sap had hardened, or was well on the way. Further, in the kiln-drying process the destructive bacteria also are killed before they have had time to attack the wood.

## Author's Closure

It is realized that the tests described in the paper are by no means exhaustive and that more tests should be made, not only of balsa wood, but also of other materials used for the same purpose. If the problem of insulating machinery so that the vibrations are not transmitted to the floor is an important one, it would be well for some committee of the Society to decide what properties of the material are important and what tests should be carried out in order to differentiate between materials.

Mr. Hoevel has pointed out that a pressure of about 20 lb. per sq. in. is usual under machine bases. The curve of Fig. 2 represents conditions much more severe, and it is probable that there would be little compression with time for a load of 20 lb. per sq. in.

Balsa wood has a modulus of elasticity very much smaller than that of any common wood, and therefore would have a proportionately greater insulating effect, even at 20 lb. per sq. in.

The specimens were very dry when tested. No measurements were made to determine the moisture content, but the material was in the laboratory for several weeks before test. It is recognized that the moisture content would probably affect the properties of any insulating material.

Some of the specimens contained the pith at the center of the tree, and this part was referred to as "heartwood." The annular rings were much farther apart near this center and the density less. The appearance of the piece was similar to that of any softwood cut across the grain and was not uniform throughout. Specimens 2-D and 2-E were selected so as to have the same density. Fig. 2 shows the remarkable similarity in strength properties of these pieces having the same density.

# Engineering Characteristics of Plywood[1]

By THOMAS D. PERRY,[2] BOSTON, MASS.

PLYWOOD is a recently adopted name for the product of an age-old art. The story of the early art has been found cut in stone in the days of the Pharaoh of the Exodus. Furniture recently discovered in the tomb of King Tut gives evidence of wonderful skill in veneering, and veneering is an early type of plywood.

Fundamentally, wood consists of bundles of slender fibers growing vertically in trees, and most fibers are substantially parallel to each other. A few fibers occur in radial directions in certain species, of which the quartered-oak "figure" is a well-known example. Wood splits with relative ease along the grain, but is most difficult to cut across the grain unless a swath or saw kerf is removed with a saw.

While much attention has been given to determining the ultimate strength as well as reasonable working limits of many materials used in the engineering trades, wood is not among those adequately demonstrated. Wood joists and timbers have had considerable testing, but smaller units have had almost no attention as to strength limits and ranges. Hence the need for this consideration of plywood possibilities.

Plywood is one kind of laminated or compound wood and consists of several sheets (plies or folds) of thin wood (or veneer) glued together, either in flat or curved shapes. Usually, but not necessarily, the adjacent layers or sheets of wood have their respective fibers or grain at right angles to each other. Obviously, internal stresses and strains are balanced in such construction, resulting in permanence of dimension and shape.

The strength increment of plywood over solid wood comes from this skilful combining of wood fibers at suitable transverse angles in proper ratios of thickness and with sufficient glue of a character suited to the ultimate utility of the plywood.

## Kinds of Veneer Used in Plywood

The thin sheets of wood or veneer used in assembling into plywood are manufactured in four ways, viz.:

- *Rotary cut* from logs revolved in a veneer lathe
- *Slice cut* from logs or flitches moved angularly against a slicing knife
- *Sawed* on a segment saw
- *Half-round cut* from flitches mounted on a wide-swing or eccentric lathe.

If these are to be arranged according to volume of production, rotary cutting (Fig. 1) will easily stand at the head of the list (92 per cent), since most plain veneers are so made as well as some figured woods. The veneer is lathe cut and spirally unrolled from the log somewhat as paper is unwound from a roll. Logs never grow perfectly symmetrical, so that a sheet of rotary veneer may show parts of several growth rings.

The straightening out or flattening of rotary-cut veneer is shown (greatly exaggerated) in Fig. 2. While logs are cooked to soften the texture before rotary cutting, yet some stretching on the concave side is essential to allow flattening. In veneer $^1/_{16}$ in. thick (and less) these cutting checks are negligible and commercially and scientifically unimportant, but in veneer $^1/_8$ and $^3/_{16}$ in. thick their presence must be recognized as an element of wood strength.

*Slicing* veneer (Fig. 3) is the standard cutting practice for mahogany and most other figured woods. The sheets of veneer are sheared from the flat surface of a hewn log or sawed flitch. These cuts extend across many or few growth rings, according to the distance from the center of the log. Sliced veneer is sometimes cut radially (quartered), but is usually cut across.

*Sawing* (Fig. 4) veneer with segment saws, although the earliest modern method, is chiefly used for quartered oak. The saw-kerf waste is usually equivalent to the thickness converted into veneer, hence the method is not economical and is applied only to woods and products that cannot be cut advantageously by any other method. About 5 per cent of all veneer is sawed.

*Half-round cutting* (Fig. 5) is done on a lathe by the use of a "stay log," an eccentric device that permits rotary cutting in a wider sweep, or with greater diameter, than when the log is mounted on the usual lathe centers. Semi-circular sheets, instead of being cut from the outside of the log toward the heart, may be cut from the heart toward the outside.

## Glues Used in Plywood

*Animal Glue.* This standard and recognized wood adhesive is sold in many grades and is made from bones and hides. It is prepared for use by dissolving it in water under moderate temperatures (140 deg. fahr.). It penetrates wood well, but is best applied in a hot room. It is soluble in water.

*Vegetable Glue.* Vegetable glue is made of a starch flour, usually tapioca flour or cassava, with water and caustic. It is prepared in a mechanical mixer by vigorous beating and cooked for some time. While in the early stages of preparation it appears to be a milky water, it later becomes a viscous fluid, rather thicker than syrup. It is economical in cost, principally used for plywood, of abundant strength, easy to use, but not waterproof.

*Casein Glue.* Casein glue is the resul. of vigorously mixing, without heat, casein (from self-soured or acid-soured milk), caustic, water, and hydrated lime. The resulting glue is a thick milky liquid, not "tacky" in its fluid form, but producing a highly water-resistant glue when dry, practically non-soluble in water. Hence it is usually specified for plywood for vessels, aircraft, and other exposed locations.

*Albumin Glue.* This consists chiefly of dried blood, mixed cold and rather gently. When applied to veneer, not over $^1/_{16}$ in. thick, it adheres due to the coagulation of the glue under action of steam-heated platens. This coagulation takes place from 175 to 200 deg. fahr., and veneer thicker than $^1/_{16}$ in. is likely to discolor from heat during coagulation. Each layer of veneer applied requires separate coagulation. This glue when property coagulated is practically waterproof and hence its use is permitted under the most rigid waterproof specifications.

*Silicate Glue.* Silicate glue consists of silicate of soda or liquid glass and is a low-priced glue used in box shooks and less costly plywood products.

There are various other less frequently used wood glues: liquid glues from fish bladders, soy-bean glue, potato-starch glues, and others, but their use in plywood is unimportant.

[1] Portions of the material herein presented were prepared by the author and published in "Veneers and Plywood" by Knight and Wulpi, Ronald Press, 1927, and are used here by permission.

[2] Director, Woodworking Division, Bigelow, Kent, Willard & Co., Inc. Mem. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., November 26 and 27, 1928.

### Plywood Assembly Procedure

Plywood glues are usually mixed mechanically and spread by revolving spreaders. The assembled plywood must go under a hydraulic press (at approximately 75 lb. per sq. in. pressure) before the initial set of the glue has begun, and remain under pressure or in clamps for not less than four hours. It is then dried, cut to size, and sanded.

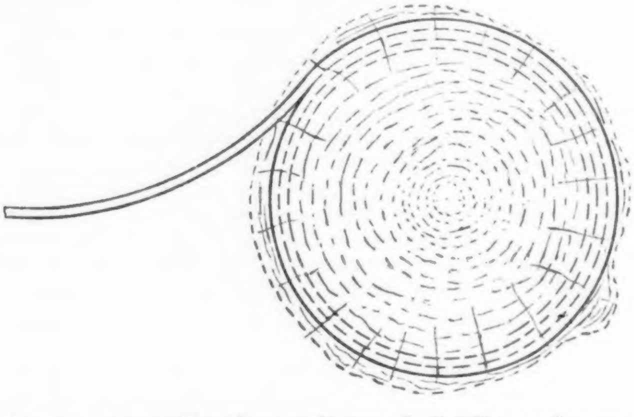

Fig. 1 Showing How Rotary Veneer Is Cut From a Log or Bolt After the Uneven Exterior Has Been Cut Away. Note the Probability of Irregular Figure, With No Two Sheets Alike

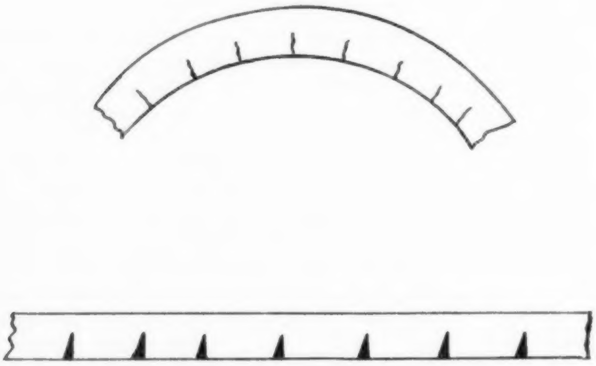

Fig. 2 Showing, Greatly Exaggerated, Why Rotary-Cut Veneer When Flattened From Its Original Curved Form Will Exhibit Cutting Checks Where the Fibers Have Been Forced Apart In the Flattening Process

### Waterproofness as Applied to Plywood

There is as yet no simple and effective process of rendering wood entirely waterproof. At the present time, certain glues are more waterproof than the wood they join together. In other words, the immersion of plywood in water will not soften or dissolve a properly made and applied casein or blood albumin glue. Such immersion, however, will eventually penetrate the openings of the wood sufficiently to shrink or swell the wood fibers enough either to tear them apart, or to tear them away from the glue. When immunity from such water saturation of wood becomes practicable, the opportunities for the development of plywood along mechanical lines will be almost unlimited.

### The Use of Plywood in Furniture

The original use of veneer in furniture and interior construction was to supply a base or inert foundation on which to mount an extremely fragile or intricately patterned thin veneer. While economically sound in principle and scientifically correct in result, this utilization gave rise to the erroneous opinion, most widely held, that veneer is used to cover up an inferior product, and therefore is superficial, and represents neither a high grade of craftmanship nor a substantial product.

Furniture manufacturers have continued this use of veneer because of the fundamental correctness of the policy from every viewpoint, but popular opinion is still reluctant to accept a mahogany-plywood table top as even the equivalent of a solid-mahogany top. The facts are, as developed from the author's twenty-five year intimate contact with wood construction, that a well-made plywood table top is mechanically and artistically superior to one of solid wood.

The original method of applying a thin veneer by hand on a white-pine core or base, with face and core grain parallel and without a right-angled cross veneer between, has been supplanted by the modern plywood construction shown on the left half of Fig. 6. In this the transverse stresses are carried by the crossed grain of the adjacent layers, and the plywood product is therefore obviously stronger, stiffer, and less likely to warp than solid wood.

In addition to this use of 5-ply in furniture, chiefly designed to furnish a substantial base for a fragile veneer as well as for matched and intricately patterned veneer effects, considerable 3-ply is used in the plain woods where strength and lightness are essential. This is shown in the right half of Fig. 6.

In the making of furniture and allied products, however, neither solid wood nor plywood is subject to anything like maximum stresses, and while the strength increment of plywood is of service, the laminations are usually to preserve the figured face of the veneer.

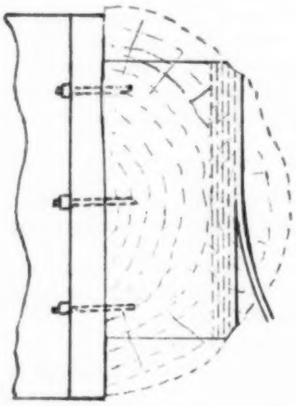

Fig. 3 Showing How Sheets Are Sliced From a Hewn (or Sawed) Log, Sometimes Halved and Quartered. Note the Probability of Almost Identical Figure on Adjacent Sheets

### Possible Strength Qualities of Plywood

The tremendous potential field for the use of plywood as a wood construction of maximum strength consistent with minimum thickness and weight, was realized only in meager outline during the development of airplanes during the war. From time to time the vigorous promotion of sheet and tubular metals has threatened to outdistance plywood, but still plywood remains as a product of remarkable utility in a wide diversity of products required by engineers.

### Analysis of Plywood Characteristics

Plywood, or laminated wood glued up with thin sheets of veneer

alternating in direction of grain, is stronger than an equal thickness of ordinary solid wood for several reasons, among which the following clearly come within the engineering field.

*Tension and Compression.* Wood will resist a much greater tension and a much greater compression per unit of sectional area in the direction of the grain (the fibers) than it does at right angles thereto.

*Resistance to Shear.* This same difference occurs in resisting shear, or the force necessary to make one part slide by another in a given plane. In shear, however, the wood will resist a greater force along a plane perpendicular to the grain than along a plane parallel to it. Furthermore, in a plane parallel to the grain it has higher resistance to shear sidewise, at 90 deg. to the grain, than along the grain. In other words, the resistance of wood to shearing is less along the grain than in any other direction.

*Bending.* There can be no bending without the development of tension and compression. Wood has a much greater resistance to bending in the direction of the fibers or lengthwise of the grain than sidewise, or at 90 deg. to the grain. If, therefore, it were possible to have an ideal form of wood construction with the fibers running in both directions, it would provide an equal strength in every direction so far as tension and compression are concerned.

Furthermore, the bending of an object of uniform thickness produces the maximum tension and compression per unit of sectional area at the outer and opposite surfaces. That is, when an object is bent there is a pulling apart or tension on the convex side and a pressing together or compression on the concave side. Somewhere between is a point at which there is neither pulling nor pressing, which is called the neutral axis. As the tension and compression are zero at this neutral axis and maximum at the opposite surfaces, it can be easily seen that a relatively small thickness at each surface supplies the great bulk of the tension and compression which together constitute the resistance to bending. That is the chief reason why a thickness of veneer, perhaps one-sixth of the total thickness of a board, placed with parallel grain on top and bottom of an inert substance, will supply nearly all of the tensile and compressive strength supplied by a solid board of equal thickness.

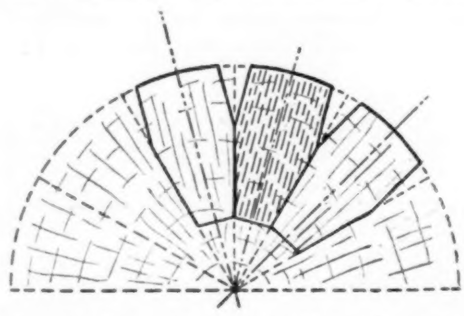

FIG. 4 QUARTER-SAWED VENEER IS MADE FROM SEGMENTAL FLITCHES, AS THE SECTIONS ARE CALLED, AND OBVIOUSLY ONLY ONE SHEET OF VENEER IN EACH FLITCH IS GENUINELY QUARTERED. THE REMAINING SHEETS HAVE ENOUGH FIGURE TO GRADE AS "QUARTERED"

*Cross-Laminations Distribute the Load.* When such a laminated board is made with similar cross-layers directly under these outer layers, the board will have a similar resistance to bending in the opposite direction, but not so great because the layers are nearer together and have the effect of a board of so much less thickness. If, however, the length of span sidewise is reduced so that its square is in the same proportion to the square of the length of the main span as the relative distance between the centers of the inner and outer veneers, approximately, the board will have practically equal resistance to bending (or equal strength) in both directions, other things being equal. The result is that the load will be distributed when supported continuously on four sides, and therefore require much less thickness in plywood than in solid wood, depending on the arrangement of the veneers and the relative length of span in each direction.

There can be no resistance to bending, even when the resistances to tension and compression are supplied, unless there is also provided a resistance to longitudinal shear. Several thin layers just placed together (without glue) will offer little resistance to bending and carry but a relatively small load because they bend independently of each other and have no bond to unite them so as to resist sliding upon each other in the direction of the span, and thus they fail to bring into use the full strength of the outer layers. This resistance is known as longitudinal shear. It is necessary, therefore, that the successive layers should be firmly bonded together into plywood by means of glue.

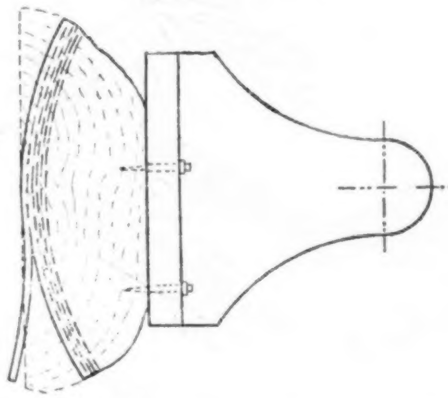

FIG. 5 ONE METHOD OF CUTTING "HALF ROUND," SHOWING HOW A CROTCH CAN BE HALVED (ON A SAW) AND CUT INTO SIMILAR ADJACENT SHEETS TO REVEAL THE BEAUTIES OF HEART-CROTCH FIGURE

Since wood, as stated before, has a greater resistance to shear sidewise than along the grain, and because this shear in bending acts in the direction of the span parallel with the top and bottom fibers, it is perfectly apparent that layers of veneer placed crosswise in plywood increase this resistance to this longitudinal shear. As wood is likely to fail as much in longitudinal shear as in tension and compression, the alternate layers of cross-veneers in plywood materially increase the ultimate resistance to bending in both directions.

*Combined Resistance.* In effect therefore, when the grains of the alternate layers are, by construction, at right angles to each other as in plywood, one layer supplies a maximum resistance either to tension or compression, and the next to longitudinal shear in one direction. Adjacent layers act with a maximum resistance in the reverse direction.

As a matter of strength of materials and of mechanics alone, the use of plywood or laminated veneers does not increase the resistance to vertical shear. Vertical shear is the tendency or force of a load on a span, acting in a direction opposite to the support, to shear across the object. When a piece is supported on four sides, however, the load is divided and passes to each pair of supports, and in this way reduces the effect of vertical shear at any cross-section.

*Influence of Glue.* The use of glue, however, undoubtedly helps this shear resistance, but as wood does not as readily show

failure from vertical shear as from the other forms of stress, transverse shear does not enter largely as a factor into this case.

The effect of using glue in bonding the alternate layers into plywood is an important factor. The application of glue to wood acts not only as a binder between surfaces, but in so far as it penetrates the wood fibers, it acts as a binder between the fibers themselves. It also provides this resistance to longitudinal

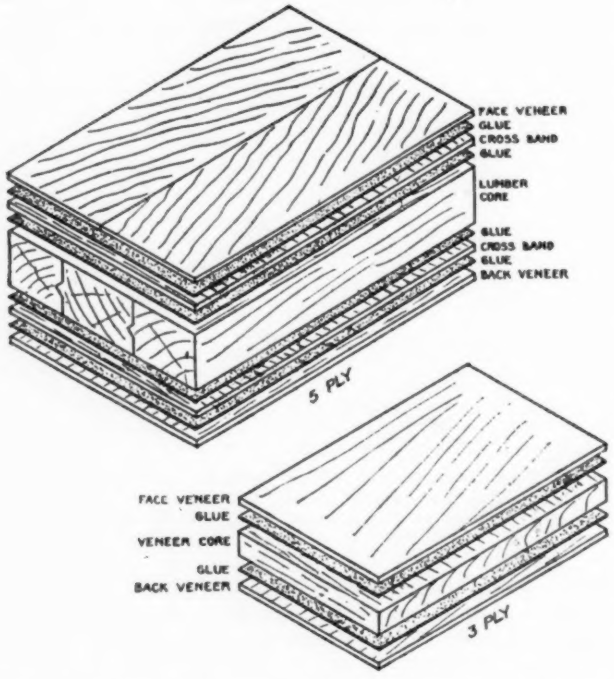

FIG. 6 SHOWING CONSTRUCTION OF 5-PLY AND OF 3-PLY, THE STRATA BEING SEPARATED TO INDICATE STRUCTURAL FEATURES, AND GIVING AN IDEA OF HOW INTERNAL STRESSES IN ALL STRATA ARE EQUALIZED IN MODERN FURNITURE DESIGN

shear, depending upon the quality of the layers, and thus increases the total resistance to all forms of stress. It does this because good glue generally is stronger than the element of adhesion that nature provides between wood fibers.

As the penetration of the glue into the wood is not great, its influence on the ultimate strength of thick layers, other than at their immediate junction, is not appreciable. In the case of such plywood construction as has been described, however, particularly inner veneer layers glued on both sides and treated under heat and pressure, the penetration is an appreciable proportion of the lamination and adds to the aggregate "built-up" plywood an appreciable resistance to all forms of stress.

Cross-veneering or cross-layers in plywood also have a tendency to counterbalance stresses and uneven shrinkage in the wood, and thereby prevent the manifestation of the internal stresses that are an element of weakness in solid wood.

*Summary.* The foregoing may be summed up in the statement that plywood made of relatively thin layers of veneer, with the direction of grain alternating, owes its valuable and economic qualities to the fact that this arrangement, properly applied, utilizes all of the strength of the wood to the best possible advantage in resisting the several kinds of stress and deformation that occur in all forms of bending and torsion.

Government tests at the Forest Products Laboratory have proved that plywood at its best is stronger per pound of weight than solid steel.

## APPLICATIONS OF PLYWOOD TO THE ENGINEERING TRADES

This multiplication of wood strength secured by the laminations of veneers into plywood opens a new field of great usefulness that has scarcely been seriously considered as yet.

*Shipbuilding.* Many are the places on shipboard, particularly passenger ships, where the sturdy strength and relative lightness of plywood together with its economical installation in large sheets make it the ideal material for bulkheads or partitions. It can be curved as much as desired when glued and can be slightly bent and twisted in installation. Shrinking and swelling are reduced to a negligible minimum by the balanced stresses in the alternately crossed plies. It is dust- and light-proof and more sound-resistant than solid wood or metal. Plywood bulkheads are usually 5-ply or 7-ply, and are cut from sheets approximately 48 in. by 96 in. long.

*Automotive Construction.* Disk automobile wheels with a web of plywood instead of metal will greatly reduce wheel weights and are already in the experimental stage, giving promise of success. Laminated side frames afford easy riding qualities to one popular make of car. Plywood bumper bars afford resilient and elastic properties and do not so easily mark and damage the opposing car as do metal bumpers. Bus and delivery body sides and tops are formed in plywood, resulting in a maximum of strength with a minimum of weight. Where larger than standard sizes are required, joints can be "scarfed" and glued together, resulting in strength equivalent to that of the original sheet.

*Airplane Requirements.* During the war, plywood of veneers proved to be light and strong, and was largely used for fuselage and wing construction. Propellers were made of another type of plywood which might be described as "laminated lumber." The speed of a propeller tip is enormous, and lightness in weight is essential to reduce centrifugal force and the resulting strains and stresses. When this country seriously undertakes the development of a protective as well as a commercial air policy, the

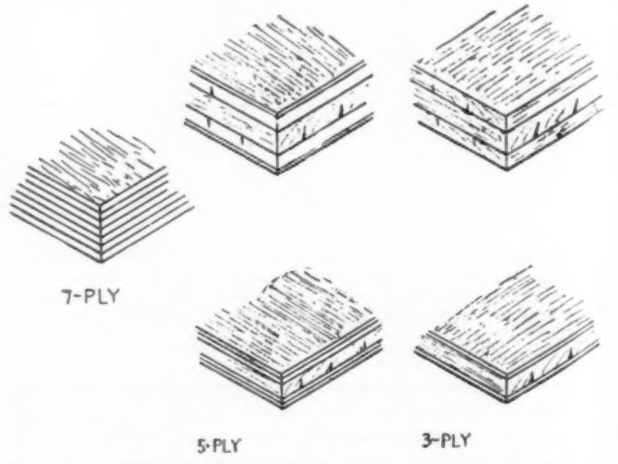

FIG. 7 SHOWING VARIOUS TYPES OF PLYWOOD CONSTRUCTION WITH DIFFERENT PLIES AND CORES

opportunity for the use of plywood in airplanes will be greatly enhanced.

*Plywood Containers.* The plywood packing case is an example of "equal-thickness ply" construction made of three thicknesses of $^1/_{20}$- or $^1/_{16}$-in. rotary-cut veneer. After gluing and cutting these sheet shooks to size they are stiffened by means of wooden strips nailed on all four edges. These reinforced sheets are set up in a case, and when so set up may be used for a wide variety of merchandise packing.

TABLE 1 OVEN-DRY WEIGHTS OF VENEER OF VARIOUS SPECIES AND THICKNESSES

(In ounces per square foot of 1-ply.)

| Species | Specific gravity based on oven-dry weight and air-dry volume | Air-dry moisture content, per cent | Veneer Thickness in Inches 1/100 | 1/80 | 1/64 | 1/60 | 1/55 | 1/48 | 1/40 | 1/32 | 1/28 | 1/24 | 1/20 | 1/16 | 1/12 | 1/10 | 1/8 | 1/6 | 3/16 | 1/4 |

Weight of glue per square foot of single glue line: blood albumin, about 0.3 oz.; casein, about 0.4 oz.

The plywood shooks weigh less than half as much as lumber box shooks and are tougher and stronger in service. Plywood packing cases are frequently used to protect plywood furniture from injury during shipping.

*Small Formed Boxes.* A process has recently been perfected in Europe in which veneer is cut $^1/_{100}$ in. thick and glued into 3-ply, resulting in $^1/_{32}$-in. plywood. This plywood can be formed in dies and cauls, after the glue is dried, just as pasteboard and thin metal are stamped. It is used for small boxes for cigarettes, cosmetics, and the like. This material as now made has a much wider manufacturing application.

*Interior Fitments.* Plywood is the only form of wood that can be used for large paneling without shrinking or swelling appreciably. Both flat shapes and curved ones can be used. This constructional utilization of plywood has suffered serious neglect.

Flush plywood doors offer an attractive and sanitary type of door for hospitals and public buildings. Plywood doors are more free from temperature and climatic change than any other type of door. Plywood doors can be interlined with asbestos or metal for fire-resistant or X-ray-proof purposes without detracting from their exterior appearance.

### Explanation of Table 1

Table 1 gives the approximate weight of individual sheets of veneer in ounces per square foot, making possible the computation of the weight of plywood built up of any combination of thicknesses and veneer species listed and of any number of plies. The approximate weights of two common water-resistant plywood glues in ounces per square foot of glued surface are also given.

It should be remembered that the weight of woods is quite variable, and that large differences from the figures are to be expected, particularly with small quantities of material.

*Example:* To get the weight of a square foot of 5-plywood consisting of 1-ply of $^1/_{12}$-in. basswood, 2 plies of $^1/_{16}$-in. basswood, and 2 plies of $^1/_{20}$-in. yellow birch for faces, at 12 per cent moisture, glued with casein glue:

$$\text{Weight} = [(1 \times 2.64) + (2 \times 1.98) + (2 \times 2.62)]\ 1.12 + (4 \times 0.4) = 14.9 \text{ oz.}$$

The example above is slightly in error through neglecting the change in volume between the moisture content at 12 per cent and the moisture listed in the table.

TABLE 2 STRENGTH OF VARIOUS SPECIES OF 3-PLY PANELS

(All plies in any one panel were of the same thickness and of the same species—grain of successive plies at right angles. In most cases eight thicknesses of plywood, ranging from $^3/_{20}$ in. to $^3/_4$ in. were tested.)

| Species | Average specific gravity of plywood based on oven-dry weight and volume at test | Average moisture, per cent | Column bending: Column-bending modulus: Parallel[1]: No. of tests | Lb. per sq. in. | Perpendicular[1]: No. of tests | Lb. per sq. in. | Modulus of elasticity: Parallel[1]: 1000 lb. per sq. in. | Perpendicular[1]: 1000 lb. per sq. in. | Tensile Test: Parallel[1]: No. of tests | Lb. per sq. in. | Perpendicular[1]: No. of tests | Lb. per sq. in. | Splitting resistance: No. of tests | Per cent of birch[2] |

[1] Parallel and perpendicular refer to the direction of the grain of the faces relative to the direction of the application of the force.
[2] The relative splitting resistance of the various panels tested depends largely on the holding strength of glue.
[3] Probably black cherry.
[4] Probably (common) cottonwood.
[5] Coast type.
[6] Probably white fir.
[7] Probably black gum.
[8] Probably (evergreen) magnolia.
[9] Probably Khaya sp.
[10] Probably tanguile.
[11] Probably silver maple.
[12] Sugar or black maple.

NOTE.—In some of the species listed above the tests are rather limited in number. Since there is considerable variation in the strength of wood, further tests on additional material would be expected to modify the values appreciably in some cases.

### Explanation of Table 2

The data of Table 2 may be used to compute the thickness of three-ply wood members of various species when the forces acting on these members are known. The strength in bending is given by the column-bending modulus, which may be used in computations in a capacity similar to the modulus of rupture of ordinary wood. The direction in which the external forces act on the member relative to the direction of the face grain of the plywood must be taken into consideration in using the data. The strength values correspond to the moisture contents listed.

### Types of Plywood Construction

Several of the more commonly used types of plywood construction are shown in Fig. 7, and a still wider range can be secured by combining veneer and lumber. Many other variations and combinations can be made in plywood construction, with more plies, or even number of plies, or angular and radial grain arrangements, each having its particular use and purpose.

*Plywood With Equal Thickness of Each Ply.* Plywood made with plies of equal thickness had a purely utilitarian origin, i.e., to use the best veneers for the faces, the next for the back, and the poorest for the inside layers, thus working up the entire product of the log. Door panels are customarily made of three thicknesses $^1/_7$ in. thick sanded down so as to fit into a $^3/_8$-in. groove, or five thicknesses $^1/_9$ in. thick fitted to a $^5/_8$-in. groove, depending on the size of the panel.

Some stock panels are made in this way, but $^1/_4$-in. stock panels are more often made with a $^3/_{16}$-in. veneer core and $^1/_{20}$-in. face and back.

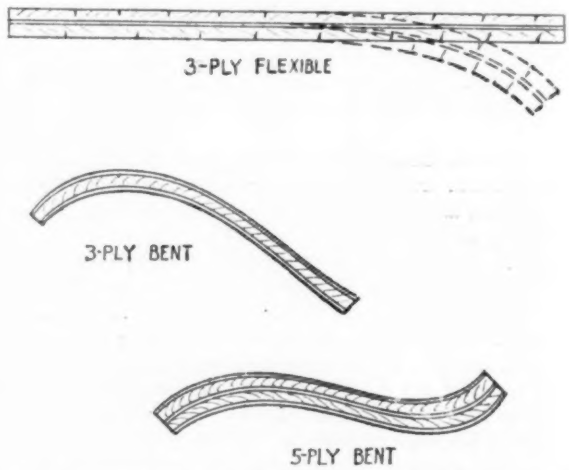

FIG. 8 FLEXIBLE AND CURVED PLYWOOD SHOWING RELATION OF THICKNESSES AND BENDING. BENDING WITH THE GRAIN IS EASY AND POSSIBLE ON THICK VENEER. BENDING AGAINST THE GRAIN SHOULD BE ONLY ON THIN VENEER

This same style of construction with plies of equal thickness is used for player-piano bellows stock and automobile instrument boards, dashboards, floor boards, and the like, although

TABLE 3 THICKNESS FACTORS FOR VENEER

[Giving: (1) Veneer thickness for the same total bending strength as birch ($K_s$); (2) veneer thickness for the same weight as birch ($K_w$).]

| Species | $D$ Average specific gravity of species[11] based on oven-dry weight and air-dry volume | Specific gravity of glued plywood as tested, based on oven-dry weight and volume at test | Moisture content of plywood as tested, per cent | $S$ Unit bending strength compared with birch,[1] per cent | $K_s$ Thickness factor for the same total bending strength as birch, $\sqrt{\frac{100}{S}}$ | $K_w$ Thickness factor for the same weight as birch, $\frac{0.63}{D}$ |

[1] Average of the column bending moduli parallel and perpendicular to grain compared to birch, based on tests of 3-ply wood, each ply one-third of the total panel thickness.
[2] Probably black cherry.
[3] Coast type.
[4] Probably white fir.
[5] Probably black gum.
[6] Probably (evergreen) magnolia.
[7] Probably Khaya species.
[8] Probably tanguile.
[9] Probably silver maple.
[10] Probably sugar or black maple.
[11] Values of domestic species taken from U. S. Department of Agriculture Bulletin 556, Mechanical Properties of Woods Grown in the United States.
[12] Based on tests not included in Bulletin 556.

the core wood often is of a different species and sometimes of a different thickness from face and back, thereby departing from the original utilitarian urge.

*Flexible and Bent Plywood.* Veneers do not bend easily against the grain, hence a flexible panel may be made with a very thin core of veneer and thick faces of loose-cut veneer. (See Fig. 8.) The old-fashioned sleigh was made using this class of plywood. The combined flexibility and stiffness of such plywood is surprising.

Bent plywood carries this flexible plywood idea one stage further. The reverse-curve opera seat should be bent rigid, not flexible, hence if a face and back of thin veneer are glued on to the above 3-ply flexible panel, it will result in a rigid bent 5-ply panel. It is, of course, made in one gluing operation and pressed and dried in nested cauls or dies.

This rigid bent plywood can also be made in 3-ply, using a thin face and back, and a thick, loosely cut core, bending the core with the grain. This is cheaper and not equal to the 5-ply seat.

*Plymetal.* Not only is it possible to produce combinations of different woods through a series of thicknesses and through various methods of assembling of wood veneers, but a new field appears in which wood-fiber board and metal may be "plied" together in various combinations. This will require a careful study of suitable glues and adhesives, but the opportunity is most promising.

### Explanation of Table 3

When substituting one species for another in airplane plywood it is desirable to know the thickness of veneer which will give either the same bending strength or the same weight as the original material. The thickness factors $K_s$ and $K_w$ given in Table 3 will be found useful for this purpose. For instance, the thickness of basswood veneer required to afford approximately the same bending strength as one-tenth inch yellow poplar, may be obtained by multiplying the thickness of the yellow poplar by the ratio of the thickness factor ($K_s$) of basswood to that of yellow poplar. The factor $K_w$ may be used in a similar computation to obtain the thickness of one species required to equal the weight of another.

### The Testing of Plywood

The possibility of using plywood in the manufacture of airplanes, fuselages, and wing-beam covers and for many purposes where heavy silk and other fabrics were previously used was a war development, and Government departments were immediately put to work investigating the subject. Starting with the proved fact that laminated wood or plywood may be stronger than steel, weight for weight, of what practical use could this have been in winning the war?

Considerable literature was developed by the Forest Products Laboratory at Madison, Wis., but the results are too new, the scope of the investigations too limited, and our perspective is too short to do full justice to the subject.

The testing of veneer was chiefly as a component part of plywood to determine what any single ply might do under various conditions. The weights of commercial species of veneer (Table 1)[3] were determined, but it was found that different trees of a single species yielded veneer of somewhat varying weights—heart wood was heavier than sap, highland and lowland growths had different textures, and so on.

Table 1 should be used in determining the approximate weights per square foot of oven-dry veneer. Utilizing the glue weight given, it is possible to compute the weight of plywood and reduce it to pounds per square foot. Table 2 is developed for the purpose of computing the approximate tensile strength of plywood per square inch. Table 3 gives thickness factors for determining the thickness required in basswood or ash to be equivalent to yellow birch.

In addition to the tables on veneer tests just described, another

[3] "Data on the Design of Plywood for Aircraft," National Advisory Committee for Aeronautics, Report No. 84, 1920.

Table 4 (from Report No. 84) is given, showing the strength of the various species of wood when made into 3-ply.

Both of these series of tests, however, relate to the development of ultimate strength in plywood and apply to airplane design rather than to other industries where abundant strength can be obtained by sufficient size and weight.

Tests of commercial glues have a much wider application than the veneer and plywood tests outlined above. The glue tests fall into two general forms, one for the constituents and qualities of the glue in powder and fluid form,[4] and the other for the strength of joints made in various ways with different glues.

The British and the United States Governments have adopted similar methods for testing the strength of a plywood glued joint. Pieces of veneer are glued up into plywood, of the size and arrangement shown in Fig. 9. The arrangements of transverse grooves is such that when the samples are pulled apart in a tensile testing machine the separation must come on either one or both of the glue lines, or in the short center piece of veneer core.

The difficulty with this test is the lack of uniformity in mixing and applying glues to different woods under varying pressures. There are too many variable elements to isolate clearly the one of glue-joint strength. This method, however, gives satisfactory comparative tests where an unknown glue is tested under

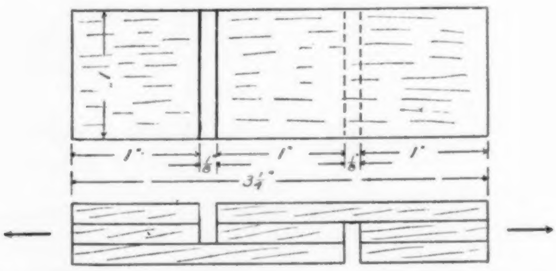

Fig. 9 Glue Test Specimen as Made for the Manufacture of Plywood, Adopted by the American and British Governments During the Recent War

similar conditions with one whose qualities are known to be satisfactory.

Another similar shear test but under compression rather than tension is usually made by gluing blocks of hard maple together and pushing rather than pulling apart.

### Explanation of Table 4

Table 4 lists the tensile strength of 3-ply wood of various common veneer species and the approximate strength of single-ply wood. The strength figures, given in pounds per square inch, correspond to the moisture contents listed.

*Sample Computation:* To obtain the tensile strength of 3-ply wood consisting of two $^1/_{20}$-in. birch faces and a $^1/_{16}$-in. basswood core:

Tensile strength parallel to face grain $= 2 \times {}^1/_{20} \times 19{,}820 = 1982$ lb. per in. of width.

Tensile strength perpendicular to face grain $= 1 \times {}^1/_{16} \times 10{,}320 = 645$ lb. per in. of width.

This computation neglects the tensile strength of the ply or plies perpendicular to the grain, which is comparatively small, and the results are therefore slightly in error.

The mechanical properties of wood are quite variable, and the strength of individual pieces may be expected to differ considerably from the average values given.

TABLE 4 TENSILE STRENGTH OF PLYWOOD AND VENEER

| Species | Number of tests | Moisture content at test, per cent | Specific gravity[1] of plywood | Tensile strength[2] of 3-ply wood parallel to grain of faces, lb. per sq. in. | Tensile strength[3] of single-ply veneer 1/2 (d), lb. per sq. in. |

### Conclusion

The engineering field offers many other openings for the economic and effective use of a plywood that is strong for its weight as well as thoroughly waterproof.

The maker and the user of plywood may well join forces in striving to bring about a better understanding of plywood in its many aspects, in an intensive development of the processes of making plywood, and a broader utilization for both economic and utilitarian purposes.

## Discussion

Charles B. Norris.[5] I would like to make a few additions to the paper, in parts that might possibly be a little misleading. The author says, "Cross-veneering or cross-layers in plywood also have a tendency to counterbalance stresses and uneven shrinkage in the wood, and thereby prevent the manifestation

[4] A bulletin describing "Standard Methods for Determining Viscosity and Jelly Strength," adopted by the National Association of Glue Manufacturers at Atlantic City, Oct. 10, 1923, may be obtained from the National Association of Glue Manufacturers, 1355 West 31st Street, Chicago, Ill.

See also "Recent Advances in Methods of Glue Evaluation," by Wilbur L. Jones, Mechanical Engineering, vol. 47, no. 11a, Mid-November, 1925, p. 1072.

[5] Mechanical Engineer, Haskelite Mfg. Corp., Grand Rapids, Mich. Mem. A.S.M.E.

of the internal stresses that are an element of weakness in solid wood." The word "manifestation" is well chosen, because the stresses are there. In fact, the internal stresses of plywood are likely to be greatly in excess of those found in ordinary wood. In some cases, where the panel is rather thick and the core is also thick with respect to the thickness of the panel, plywood panels have large longitudinal shear stresses due to the internal forces built up. But these stresses in plywood are balanced so that they do not tend to warp the plywood. They are balanced in the degree that when the panels fail in longitudinal shear, they show no signs of warping until the failures have actually occurred. Then, of course, there are some signs of warping.

The author also says, "Since wood, as stated before, has a greater resistance to shear sidewise than along the grain, and because this shear in bending acts in the direction of the span parallel with the top and bottom fibers, it is perfectly apparent that layers of veneer placed crosswise in plywood increase this resistance to this longitudinal shear." The meaning of that paragraph evidently is that the likelihood of failure in longitudinal shear is decreased. It is; but another factor is involved—the rigidity of wood is much less across the grain than with the grain. Therefore in a piece of plywood there is a much greater tendency for the layers to slip over each other than would be the case if the layers were glued with the grain of all layers lying in the same direction. This means that the wood, under certain conditions, could be bent without inordinately increasing the compression strains that would naturally result from such bending.

In another place the author says, "When such a laminated board is made with similar cross-layers directly under these outer layers, the board will have a similar resistance to bending in the opposite direction, but not so great because the layers are nearer together and have the effect of a board of so much less thickness." This is approximately true in the average case of plywood panels, say three-ply panels, where the faces have about the same longitudinal thickness as the core. There are some special cases, however, which are important enough to be considered. For instance, it is evident that a piece of three-ply plywood, having a core which is thick compared to the thickness of the total piece of plywood and having very thin faces, will act like a board whose grain is in the direction of the core. On the other hand, a piece of three-ply plywood with an exceedingly thin core and thick faces will act like a board whose grain runs in the direction of the faces. Undoubtedly somewhere between those two limits there will be a construction of three-ply plywood which will have exactly the same strength in both directions. In fact, such a construction can be rather readily determined mathematically. Also, between these two extreme constructions, there is a construction of plywood that has the same stiffness in both directions.

It is interesting to note that if the problem is analyzed mathematically the construction for equal stiffness in both directions is found not to be the same as that for equal strength in both directions. It is important to call attention to this fact because the real advantage in plywood is that the construction can be designed to suit the particular purpose the designer has in mind.

In discussing albumin glue, the author says, "This coagulation takes place from 175 to 200 deg. fahr., and veneer thicker than $^1/_{16}$ in. is likely to discolor from heat during coagulation." We have found that discoloration can be controlled by controlling the temperature. In fact, faces of plywood as thick as $^1/_4$ in. can be glued without any discoloration.

The author adds, "Each layer of veneer applied requires separate coagulation." That limitation also has been overcome. We often glue up seven- and five-ply panels in a single operation.

C. W. Coye.[6] It would be unseemly for a non-technical representative of a comparatively non-engineered industry to discuss in technical detail the paper just presented. The author has touched on a few of the many factors involved in the production of plywood, indicating that his profession has a thorough understanding of them and the need for further study of plywood production and use, control of production factors, further development of comparative tests, and research of partially developed and potential markets.

Every new or partially developed use for any product must go through an experimental stage with the cooperation of both the consuming and producing branches. It is during the development or experimental stage that both factors need the kindly guidance of the engineering profession.

It is perhaps safe to say that only recently has the woodworking industry in its several branches been discovered as a fertile field by the strictly technical profession. As yet a great many, perhaps the majority, of the large commercial units in the woodworking industry are without the benefit of technical advice from within their own personnel. While many manufacturers of the thousands comprising the woodworking industry have at least one technical man on their staff, the bulk of them are dependent upon outside advices or, as is done largely, accept what is brought to them without studying any of the technical phases of the material. Some of these technically uneducated commercial units comprise a very large market for plywoods of various sorts, but because of the lack of any definite basis to purchase on and because of insufficient study of their plywood requirements they have selected materials with which they have had unfortunate experiences. Such experiences have weakened their faith, and even though its superior appearance value stimulates trade, the manufacturer of the product finds the replacement of plywood parts so heavy that he hesitates to use it in his goods.

It is not unreasonable to expect that eventually research and dissemination of the results will progress to the point where the large markets, both in the engineering and the commercial fields, can purchase on a detailed specification basis with a consideration of all factors of production and use involved. Already there are standards for the production of plywoods for the aircraft industry, and it is bought largely on a specification basis. It is true that the standards have been fostered by the Government, but most of the users of aircraft plywoods use the same standards.

The engineering profession has indicated the possibilities of study in the plywood-producing industry and has made great strides in analyzing the engineering characteristics and possibilities of the material. The next step must be one of further study and a translation of the results into standards for both the technical and non-technical user.

Many companies are forced to accept material brought to them without technical research and advice and without a thorough knowledge of whether that material is particularly suited to their uses. There are many instances where certain branches of the woodworking industry have selected plywoods because of their appearance value and because their trade demands the appearance value a plywood assures, and have had very unfortunate experiences with it and have been forced to use less of it or to cease using it entirely, even in the face of a large demand for that particular product.

Plywood is being purchased for specific purposes and from, I might say, specific units in the plywood-producing industries on a specification basis. It is not unreasonable to asume that, later, plywood can be engineered or that standards can be set up so that any industry can buy the plywood for a particular purpose on the specification basis. This to me is the outstanding feature of the paper. An engineering knowledge of plywoods has

[6] Alaska Refrigerator Co., Muskegon, Mich.

been established and that it should be further developed is necessary so that it will be possible to buy on the specification basis.

In the refrigerator industry there has been a large call for plywood doors because of the smooth appearance that it gives to the refrigerator. One factory used perhaps two cars of plywood last year, and the replacement was about 10 per cent. This is not an unsolvable problem, but the company has been forced to discontinue the use of plywood entirely because the plywood they had been using had not been properly specified, because they were without technical advice in their own industry, and because the plywood producers were unable to give them that technical advice.

C. S. Welch.[7] A discussion of plywood which would be impervious to atmospheric changes, possibly through impregnation, would be of very great interest, and I am of the belief that very little has been done along this line in the manufacture of plywood.

The author stresses the point that very little has been done in substituting plywood for solid wood in most of our manufacturing for engineering purposes. This is entirely true, and the next few years will bring forth uses of plywood in cases where now no thought has been given to this possibility.

Ralph K. Merrill.[8] In his description of the uses of plywood, the author gives a number of the properties of plywood when used in building stateroom partitions on board ship. He makes the statement that the resistance to the transmission of sound is greater than solid wood or metal. Are we to take that as meaning that it is less likely to absorb sound or to reverberate, i.e., to reflect sound?

Furthermore, some definition of the terms "plywood" and "veneered" panels should come out of this meeting. It should be clearly stated where one leaves off and the other begins, if it does begin at all; whether we are to consider that the panel made up of a very thick core, such as Mr. Norris has referred to, and covered with a thin sheet of wood, is to be known as a veneered panel or a plywood panel and whether such panels are now good practice in the furniture trade or any other.

Undoubtedly, the three-ply with a very thick core makes a panel which is in itself very superior to solid wood, regardless of what the wood may be, in its resistance to warping, checking, swelling, and so on.

I have noticed that on the edge of a piece of seven-ply plywood, say $^{13}/_{16}$ in. thick, the plies are quite visible, and the wider the panel, the more visible they become. Is this a characteristic of plywood or is it due to extreme haste in manufacture, indicating the lack of drying the center plies in the present type of plate dryer, or is it because it was sanded and finished too soon after it was glued?

D. J. McLaughlin.[9] I was a little disappointed that the author had nothing to say about the preparation of cross-banding and veneer for laying and the redrying of the cores before laying finished veneer. Mr. Norris has said that the five-ply and seven-ply are sometimes built up in one operation. On the other hand, on a large table-top construction, it has been our practice to build the plies separately, redrying after each gluing operation, to guarantee a minimum of shrinkage in the finished work. My suggestion would be that at some future date we have a paper on drying and redrying which is so important a part of properly building plywood.

[7] The Brunswick-Balke-Collender Co., Muskegon, Mich.

[8] Industrial Mechanical Engineer, American Seating Co., Grand Rapids, Mich. Mem. A.S.M.E.

[9] Superintendent Wood Division, Yawman-Erbe Mfg. Co. Assoc-Mem. A.S.M.E.

Mr. Norris. In speaking about gluing five- and seven-ply panels in one operation, I should explain that the panels were intended for structural purposes and not for furniture. It was not necessary that they be good looking. In regard to the terms "plywood" and "veneer," during the war or shortly afterward the Forest Products Laboratory, which is a Federal Government institution, decided to call all panels built up of veneer "plywood" and to call the different layers themselves "veneer."

D. Olander.[10] In regard to moisture-proofing wood we have tried out a process, and in the case of one species of wood it was apparently possible to reduce swelling practically completely. In general the reduction amounted to 50 per cent or more.

I believe the possibilities are very good, providing sapwood is used and also with the heartwood of certain species. It is a preservative process and seems largely a question of getting enough of the preservative into the wood. We tried some Sitka spruce which had been treated and found that at a relative humidity of 88 per cent which was maintained for several weeks there was no indication of swelling so far as we could measure.

O. M. Dunton.[11] In line with Mr. Merrill's remarks as to the expansion of plywood due to the internal stresses, and also in line with Mr. Welch's first paragraph, I recall an article on plywood which told of a study which was being made on closing the pores and making it impervious to moisture. This process is the impregnation of plywood with chemicals which will make it impervious to moisture. I am wondering what success has been made along that line, if any.

William Braid White.[12] A word was said about sound transmission through solid woods as compared with the same process through plywoods, and again with reference to the general question of reflection or absorption. In the first place, very little work has been done on the subject.

Secondly, if transmission through a piece of wood is meant, then it follows that the more the plywood is built up or the more plies there are in the plywood, the less transmission there will be through them, so that transmission in the case of plywood would be very small indeed, probably negligible as compared with metal.

Thirdly, reflection of sound, other things being equal, becomes solely a question of the surface hardness. If, therefore, the outer ply of a piece of plywood is of the same species as the solid wood, other things being equal, their reflective qualities will be the same. The height of the index will depend entirely upon the surface hardness. That also will apply to metal. Other things being equal, a sheet of steel, for instance, will have a higher reflective index.

On the other hand, reversing the effects, a parallel result will be found with regard to absorption. If it is desired to absorb sound, other things being equal, more will be absorbed from any known wood, except possibly one or two of the extremely hard woods, than from steel.

### Author's Closure

Mr. Merrill raises the question of the sound-resistant qualities of plywood compared with metal or other wood. I think, compared with metal, plywood will not transmit sound as will metal. Neither will plywood transmit sound as well as solid wood. Mr. White has covered this in his discussion.

On the question of the proper use of the terms "veneer" and "plywood," I believe the term "veneer" should be applied to thin

[10] Baldwin Company, Cincinnati, Ohio.

[11] American Seating Company, Grand Rapids, Mich.

[12] Consulting Acoustic Engineer, American Steel & Wire Co., Chicago, Ill. Mem. A.S.M.E.

single sheets and that as an adjective the word "veneered" is misleading. Plywood is made up of sheets of veneer. If this phraseology is used, much confusion will be avoided.

With regard to the value of three- or five-ply plywood, there is no question that five-ply is better than three-ply, but it is also more expensive. I think that the value of three- or four-ply in certain products rests largely on an economic base.

Many attempts at impregnation of plywood have been made, but in every instance that I know of impregnation has added so much weight that it has largely eliminated the strength-for-weight advantage. That is, anything that fills the pores of the wood and renders it impervious to moisture adds so greatly to the weight as to throw plywood out of its particular function. There are quite a number of such processes.

There are some other developments in certain research channels looking toward gaseous impregnation of woods, with a later liquefaction or solidification of those gases in the pores of the wood by another gas, a much lighter impregnation than is possible by the liquid processes. The process is in the laboratory stage now, and no one can predict what will come of it.

# Efficiency Methods and Standards in German Woodworking Industries

## A Brief Description of Work Being Carried on in Germany for the Purpose of Attaining Higher Efficiency in Woodworking

By ROBERT SCHLUETER,[1] GERMANY

IN ADDRESSING mechanical engineers there is no need to explain the necessity of obtaining greater engineering efficiency in industries, no matter where located, in the United States, in Germany, or elsewhere. It has been the engineer who has originated research and technical supervision in the industrial field, with the aim of obtaining better quality, lower costs, and greater safety.

In 1921 the Verband Technisch-wissenschaftlicher Vereine (The Association of Technical and Scientific Societies) in coöperation with the German Government's Department of Economics, started the Reichskuratorium für Wirtschaftlichkeit (German National Committee for Promoting Industrial, Commercial and Agricultural Efficiency), generally called the "RKW." This association works under the auspices of the German Government, but is entirely controlled and managed by the industries themselves through committees made up of experts in the various above-mentioned industries. The government provides the expenses of management. The cost of research is usually contributed by the industry concerned, either in cash or by sending engineers and other experts to the different meetings and conventions of the RKW.

The RKW works through its *Ausschüsse* (committees) which operate in direct connection with the different groups in industries, commerce, and agriculture.

Fig. 1 gives an idea of the organization of the RKW. But it must be understood that this sketch shows a very small part of the committee's activities, just enough to illustrate its relation to the woodworking field.

It goes without saying that none of these sub-committees works for itself, but all interchange their results among themselves and with the committees representing other lines, as, e.g., the committees on technical teaching, organization, textiles, forging, welding, etc.

FIG. 1 ORGANIZATION OF THE RKW (GERMAN NATIONAL COMMITTEE FOR PROMOTING INDUSTRIAL, COMMERCIAL, AND AGRICULTURAL EFFICIENCY)

The best way to explain the work done by the sub-committees will be by means of some examples.

The Unterausschuss für Normung in der Holzindustrie (Sub-Committee on Standards in Wood Industries), together with the Verband deutscher Holzbearbeitungsmaschinen-Fabriken (Association of the Manufacturers of Woodworking Machinery), works on standards for interchangeable parts of woodworking machinery, having first revised all the published standards for machinery in the other industries with respect to their application to the woodworking field.

Fig. 2 shows the adopted standard for cap nuts for the spindles of shapers. No matter what kind of shaper one buys, these cap nuts will always be the same and interchangeable. The engineer, the man out in the field, will understand what a big advantage

this is. The figure shows just one out of numerous standardized parts of shapers. These standards are published and copyrighted by the Deutscher Normenausschuss (German Committee on Standards), and printed by the Beuth-Verlag, G.m.b.H., Berlin S 14.

The Unterausschuss für wirtschaftliche Fertigung in der Holzindustrie (Sub-Committee on Economical Manufacturing in the Wood Industries), besides its work on manufacturing methods and on machinery (the right machine in the right place), carries on research work on saws and knives. Fig. 3 is a reproduction of specifications for research on circular saws, showing plainly how many different factors have to be considered to get real practical results. The necessary

experiments are then made in various factories. The sub-committee gathers, coordinates, and classifies the data of the experiments, sometimes being assisted in this work by the universities and *Technischen Hochschulen* (technical colleges). The results are then printed and distributed to all interested parties. These data do not relieve woodworking engineers from the necessity of doing their own research work. Rather, they supply bases from which to start. On the other hand, as is generally known, if one should ask five different foremen concerning the best shape of tooth for a certain kind of wood with a given moisture content, he would get at least six different answers, probably all of them more or less erroneous.

Another task of this committee is to settle the terminology, i.e., coin names for different methods and materials which can be universally understood. This very delicate work is much appreciated by those who have to write about woodworking and have to address an audience scattered all over the country.

The Unterausschuss für Lieferungsbedingungen in der Holzindustrie (Sub-Committee on Specifications for Raw Materials in the Wood Industries) is publishing, e.g., *Lieferungsbedingungen für Haut-, Leder-, Knochen- und Mischleim* (Specifications for Animal Glues), and is preparing specifications on soft and hard woods.

Der Unterausschuss für Arbeitszeitermittlung in der Holzindustrie (Sub-Committee on Time Studies in the Wood Industries) is making time studies on woodworking machinery and methods, thus supplying data for the precalculation of, say, a certain piece of furniture, the proper piece-work rate to employ, etc.

Fig. 4, which has been taken from Dr. Oswald Beck's *Die Stückzeitberechnung für Holzbearbeitungsmaschinen* (Time Studies on Woodworking Machinery), published under the auspices of the Sub-Committee on Time Studies, gives a number of curves showing the actual time consumed in boring holes of various diameters in hard wood. Special diagrams have also been drawn showing the time required in putting on and taking off wooden pieces of different sizes.

The Unterausschuss für Förderwesen in der Holzindustrie (Sub-Committee on Handling Materials in the Wood Industries)

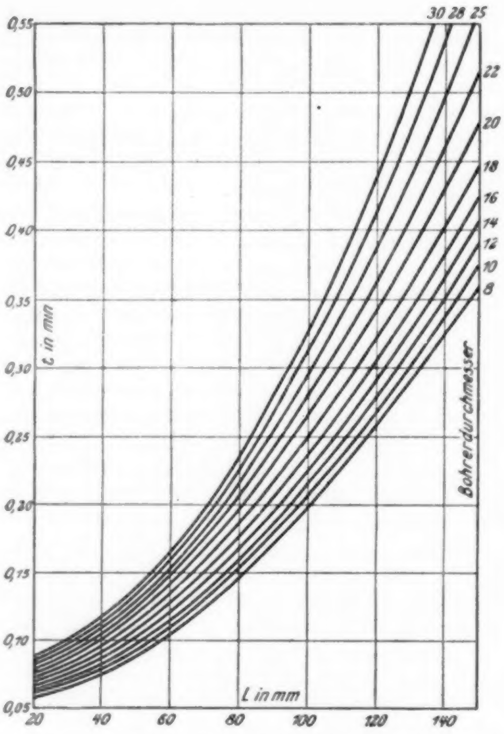

FIG. 4 CHART SHOWING TIME REQUIRED TO BORE HOLES OF VARIOUS DIAMETERS AND DEPTHS IN HARDWOOD

is investigating methods for handling logs in the saw mill, lumber in the yards, etc.

The results of the work of the RKW, with discussions of the various problems dealt with, are published monthly in the *RKW-Nachrichten* (RKW-News) and in the *AWF-Nachrichten* (AWF-News). Both journals may be obtained from the Nachrichtenstelle des Reichskuratoriums für Wirtschaftlichkeit, Berlin NW 6, Luisenstrasse 58.

Woodworking is no longer the cut-and-fit art it used to be. The evolution of the wood industries into engineering arts proceeds steadily, and as a result there comes a demand for cooperation, not only between the different branches of the wood industries of one country but between the industries of different countries, as e.g., the United States and Germany. It is the desire of the German committees to get in touch with those in America who are traveling the same roads, and the author would be very glad if this paper might contribute toward initiating such technical coöperation.

This short description of an important movement in the industrial development of Europe owes its origin to the interest of P. H. Bilhuber, Secretary of the Wood Industries Division of The American Society of Mechanical Engineers. The author is indebted to William Braid White, Chairman of the Wood Industries Division, for kind assistance in preparing this paper.

## GLOSSARY OF GERMAN TECHNICAL TERMS USED IN WOODWORKING

In order to render more intelligible Figs. 2, 3, and 4, the following glossary of German technical terms is appended:

*Abteilung.* Department.
*Anschrägwinkel.* Beveling angle.
*Art.* Kind.
*Auflockerungskoeffizient.* Factor showing increase of volume of the sawdust.
*Bemerkungen.* Remarks.
*Beobachter.* Observer.
*Betriebsleiter.* Superintendent.
*Bezeichnung.* Designation.
*Blattdurchmesser.* Diameter of blade.
*Blattstärke.* Thickness of blade.
*Feuchtigkeit.* Moisture.
*Firma.* Firm.
*Fräsdorne.* Mandrels.
*Fräsmaschinen.* Shapers.
*Freiwinkel.* Clearance angle.
*Güte der Schnittflache.* Quality of surface of saw cut.
*Gewinde.* Thread.
*Hakenschlüssel.* Hook spanner.
*Hartholz.* Hardwood.
*Holzangaben.* Wood specifications.
*Holzbearbeitungsmaschine.* Woodworking machine.
*Keilwinkel.* Angle of tooth point.
*Kreissägeblatt.* Circular-saw blade.
*Länge.* Length.
*L in mm* (Fig. 4). Depth of hole in millimeters.
*Lochbohren.* Drilling.
*Lückenfläche.* Tooth space.
*Maschinenangaben.* Machine specifications.
*Maschinenzeiten.* Cutting times.
*Maximale Schnitthöhe.* Thickest board to be cut.
*Maximale Schnittbreite.* Widest board to be cut.
*Messerdorn.* Mandrel.
*Photo.* Photograph.
*Riemenscheibe, Motor.* Pulley of motor.
*Riemenscheibe, Sägewelle.* Pulley of saw arbor.
*Riemenscheibe, Vorschub.* Pulley of feeder.
*Sägewelle.* Saw arbors.
*Schliff.* Kind of grinding.
*Schnittwinkel.* Cutting angle.
*Schnittgeschwindigkeit.* Cutting speed.
*Schnittbreite.* Saw kerf.
*Schränkung.* Width of set.
*Spanwinkel.* Hook of tooth.
*Spindelgewinde.* Thread of the spindle.
*Spindelkopf.* Spindle head.
*Spiralbohrer.* Twist drill.
*Stärke.* Thickness.
*Teilung.* Pitch.
*Tischmasse.* Measurements of table.
*t in min.* (Fig. 4). Drilling time in minutes.
*Überstand der Säge.* Projection of saw blade above board being cut.
*Überwurfmutter.* Cap nut.
*Untersuchungen.* Researches.
*Umdrehungen des Motors.* Revolutions of the motor.
*Umdrehungen der Sägewelle.* Revolutions of the arbor.
*Umdrehungen der Vorschubwalzen.* Revolutions of feed rollers.
*Versuch.* Experiment.
*Vorschub.* Feeding speed.
*Werkzeugangaben.* Specifications of tools.
*Zahnhöhe.* Height of tooth.
*Zähnezahl.* Number of teeth.
*Zweck.* Purpose.

# Discussion

PAUL H. BILHUBER.[2] It may be of interest to explain how this paper came to be written. One of the research projects of the Wood Industries Division has to do with standards for saws and knives. The committee organized to carry on that work has been busy on this large and comprehensive subject. It will submit a progress report at this meeting. In connection with this work, it seemed desirable to get information on the subject from other countries. The opportunity came last summer when a German engineer visited this country. He was identified with the governmental bureau which was to set up in Germany an organization to deal with questions of this sort. This engineer was Mr. Robert Schlueter, and he consented to write this paper, giving a brief outline of some of the work in Germany.

The paper will repay careful study because it is an example of work already done and work that will take some years to complete. A competent staff of experts is working on this project, but the very important and vital element which supports it is the German Government. The Germans are particularly interested in work of this nature because it is realized in Germany that the woodworking-machinery industry, in so far as design, output of machines, construction, electrification, and high rates of speed and feed are concerned, has as a result of the war lagged behind the progress made in other countries, notably our own and Sweden. With their accustomed thoroughness, the Germans are going hard after it, and they want to beat us if they can.

M. D. BALDWIN.[3] It may be postulated that any problem of standardization is attractive to the engineer. The engineer

[2] Assistant Factory Manager, Steinway & Sons, Long Island City, N. Y. Assoc. A.S.M.E.

[3] Vice-President, Oliver Machinery Company, Grand Rapids, Mich.

specializing in the application of his profession to the economical working of woods is no exception. The author states that in Germany sub-committees for the woodworking-machinery industry operate under general committees, in turn under the German national committee, for promoting industrial, commercial, and agricultural efficiency, and that these sub-committees are functioning today toward standardizing certain interchangeable parts of woodworking machinery, and that these committees are planning very extensive additional items for interchangeable manufacture. It is to this part of the report that the following remarks are directed.

It is not believed that any exception will be taken by any one on the efforts for research affecting cutting possibilities of saws, knives, boring bits, and the like.

In Germany, as in Great Britain and Europe generally, the development of woodworking machinery has followed quite different channels from the development here in America. In Europe materials are conserved while labor is cheap. In America materials are cheap and labor is high. Developing naturally along economical lines, under the circumstances, America has developed heavy-production and single-purpose machinery, whereas the European practice has evolved general-purpose equipment covering a multitude of uses.

The shaper in America has a function too well known to warrant description. The shaper in Europe, however, not only performs as a shaper as we know a shaper, but it is also equipped with sundry appliances making it a molder, a router, a tenoner, a flooring matcher, and what not. Again the hand jointer is as likely as not to be found in combination with a surfacer or thicknessing machine and so it goes.

It is difficult to see how the practice of standardizing particular parts within the woodworking-machinery industry, other than saws and knives, will confer a benefit commensurate with the effort of standardization.

A project which may be readily possible in a country of relatively small geographic size like Germany may be difficult of accomplishment in this large country of ours. In the United States where a machine purchased last November may be in the scrap heap tomorrow, due to the advances in the manufacturing art, such standards become limitations to efficiency as we understand the word.

In other words, the best thing for the purpose at hand is the American practice, rather than a compromise made in the interest of a theoretical advantage of interchangeability throughout the nation.

Finally, the engineer in the woodworking practice in this country is keenly favorable to research, the object of which is increased output, safety and convenience to the operator, quality, accuracy, and interchangeability of product, but he is little concerned with the infinitesimal returns to the industry theoretically brought about by standardization of machinery parts.

J. D. Wallace.[4] It requires no discussion in American engineering circles to prove that facts are more valuable than guesses in any industry. The progress made by Germany in industrial research is known to all, and the outline submitted by the author reveals an interesting alinement of his Government with technical organizations and industrial concerns which explains the widespread success of such enterprises in Germany.

The shortcomings of the United States along these lines are equally well known to us. In this country manufacturers cannot carry out a program such as outlined by the author, because our laws probably make the procedure illegal. It is a well-known fact that only the unofficial interposition of the Department of Commerce by Herbert Hoover has made possible the standardization enterprises which have recently been conducted in cooperation with various trade associations.

The present condition of each nation calls for neither excessive praise nor excessive recriminations; each proceeds on the plan dictated by its own requirements and economic position. Here in America we are highly individualistic and by temperament are skeptical of laborious research which our rapidly changing conditions may render obsolete before it is available for use.

There is need in Germany as well as here for original research as a basis for standardization; too frequently exhaustive tests are predicated on empiric figures which are anything but accurate. In the woodworking industries, as an example, no authoritative facts are known about the fundamental characteristics of wood sufficient for a proper starting point in the problem of its fabrication into useful commodities.

Woodworking is an old industry; so old that many of its processes have been handed down from grandfather to father and to son; and habits acquired before the age of scientific inquiry are hard to root out. Woodworking operations lend themselves easily to small-scale production, bringing into the industry numerous concerns too small to pay for expensive research. The material used is irregular in structure and lacks uniformity under various conditions of age and climate.

For these and other reasons the facilities of most research bodies in this country are taxed in the pressing business of securing highly specialized information that is only indirectly of fundamental value.

Despite the absence of a sound theoretical basis on which to work, American woodworking industries blunder through to successful results that are in nowise inferior to German achievements. We start out with the acknowledged advantage that in business a "doer" generally accomplishes a great deal more than a thinker. We prove the truth of the statement of our great philosopher Will Rogers that "one man digging is better than one hundred committees sitting."

The attention of our woodworking interests are today centered on the greater possibilities of saving by mass production and a wider extension of market. One thousand dollars spent for advertising or improved equipment will bring more profit than the same amount of money spent in research under present conditions, and it is likely this condition will continue until our economic situation changes greatly.

The author rightly says, "Woodworking is no longer the cut and fit art that it used to be." We could well afford to exchange with Germany some of the individualistic products of our genius for the stabilizing results of their profound research. To effect this exchange we have need of some agency to provide authoritative translations, because at the present time the subject matter of German publications is practically unavailable to the ordinary American manufacturer.

The Wood Industries Division could perform a valuable service by formally accepting the invitation of the author to cooperate, to make frequent translations of the material specified in his paper, and to distribute it generally among engineers of this country.

# Automatic Production of Small Wood Parts

By I. B. Whinery[1] and G. A. Whinery,[2] Grand Rapids, Mich.

*The authors point out that more attention has been given to the design of hand-fed and manually controlled general-purpose machinery for woodworking than to the building of automatic machines. Among other reasons it is shown that the set-up time is generally long as compared with the working time because of the rapidity with which wood can be worked.*

*As examples of automatic woodworking machines the authors describe three: (1) A knob-tapping machine, chosen to show how production may be increased by performing a single operation more rapidly than the best operator could do it by hand; (2) a square-knob blanking machine to illustrate the combination of several distinct operations in one mechanism; (3) a rosette machine as an example of one the primary purpose of which is to achieve quality without sacrificing speed.*

*The economic principles involved in the use of automatic woodworking machinery are discussed in the remainder of the paper.*

For a number of very apparent reasons, woodworking machine builders have given much more attention to the design of hand-fed and manually controlled general-purpose machinery than to the building of automatic machines. In general, metal-working machinery builders have found many more applications for the automatic principle than have builders of machines to work in wood.

One reason for this is the relatively small number of wood parts required to be manufactured. With the exception of matches and toothpicks, which are not, strictly speaking, wood parts, there is no article made of wood the production of which approaches in quantity that of such items as screws, bolts, nuts, nails, and a number of other metal parts which might be enumerated.

Another contributing factor to this situation is the fact that even by means of unspecialized machinery, operated manually, wood parts can be produced relatively rapidly. With so elementary a machine as an ordinary hand turning lathe, simple wooden turnings can often be produced more rapidly than the same shapes could be turned out of metal in an automatic metal-working lathe. Due to this, it is more difficult to save enough time with an automatic woodworking machine to make it a good investment than in the case of a machine for working in metal.

A corollary to the rapidity with which wood may be shaped on simple machines is the relatively long period required to set up an automatic wood-turning machine in comparison with its running time. Unless a considerable number of parts can be run at one set-up, it often takes less time to produce the parts on general-purpose woodworking machinery than to set up an automatic machine.

However, it must not be concluded that the automatic field has been entirely neglected by the machine builders. There are standard machines on the market for the production of such turnings as dowels, insulator pins, clothes pins, spools, and bobbins. Wedges are now made by means of automatic machinery, and a number of machine manufacturers build automatic feeding mechanisms which can be incorporated in shapers and other woodworking machines, lending themselves readily to the production of small wood parts.

[1] Manager, Waddell Manufacturing Co. Assoc-Mem. A.S.M.E.

[2] Superintendent, Waddell Manufacturing Co. Jun. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., November 26 and 27, 1928.

The basis of the material to be presented in this paper is a group of automatic machines which have been developed for the manufacture of wood ornaments for furniture. They are interesting because there are a number of factors to be considered in connection with machinery of this type which do not exist in the better-known types of automatic machines, such as automatic turning machines of various kinds.

The machines which have been selected for discussion in this paper are taken as typical machines; that is, they illustrate principles which apply to automatic woodworking machinery as a whole. A knob-tapping machine has been chosen to show how production may be increased by performing a single operation

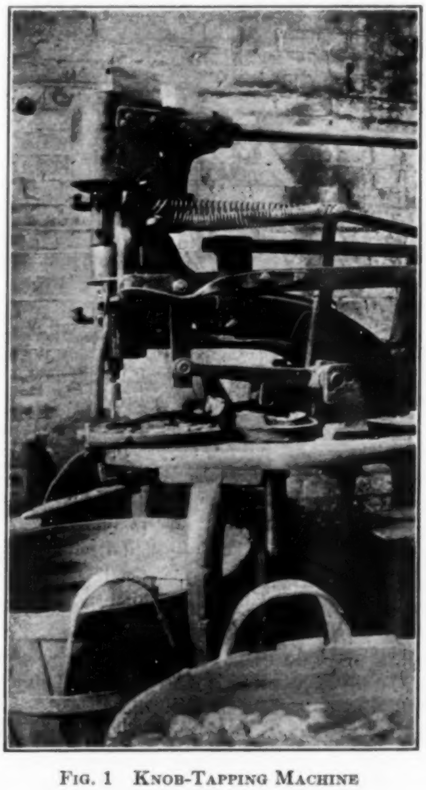

Fig. 1 Knob-Tapping Machine

more rapidly than the best operator could do by hand; a square-knob blanking machine illustrates the combination of several distinct operations in one mechanism; and a rosette machine is an example of a machine the primary purpose of which is to achieve quality without sacrificing speed.

### Knob-Tapping Machine

An example of an automatic machine which performs only one operation, but does that one much more rapidly than could be done by hand methods, is the knob-tapping machine illustrated in Fig. 1. Fig. 2 illustrates the operation this machine performs. Round knobs are furnished to the machine with the screw-holes bored, but not tapped. The operator places them in holes which are spaced around a horizontal disk and which are just large enough to allow the knobs to drop in easily, with the hole up. A cam operates a finger which indexes the disk so that

each hole stops directly underneath a vertical tap. The spindle on which this tap is located rotates and moves up and down at the same time, the mechanism being so arranged that during the descending stroke the tap tends to screw into the knob and during the rising stroke the tap revolves in the opposite direction. The speed with which the tap moves up and down is regulated according to the lead of the tap.

When the machine is in operation, the attendant places the untapped knobs in the holes in the disk as they come past his

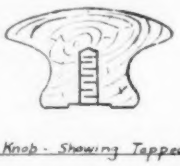

FIG. 2 SECTION OF KNOB SHOWING TAPPED HOLE

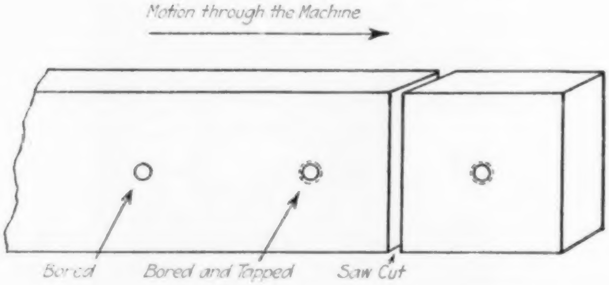

FIG. 3 STEPS IN MAKING SQUARE-KNOB BLANK

side of the machine. The machine indexes the disk around, one hole at a time, bringing each knob directly underneath the tap and holding it there until the tapping operation is completed. As each knob stops to be tapped, a jaw swings against it from one side, clamping it to prevent its turning with the tap. A little further on in the circle is a hole underneath the disk through which the tapped knobs drop into a receptacle. A pushing rod fastened to the spindle frame and moving up and down with it pushes out of the disk any completed knobs which may fail to drop out of their own accord.

This machine is relatively simple in its construction, but it performs the tapping operations at least twice as rapidly as could be done by hand. Instead of having to perform a number of movements, the operator is relieved of all motions except placing the untapped knobs bottom side up in a hole in a plate.

### SQUARE-KNOB MACHINE

The next type of automatic machine to be discussed is one in which several operations are performed by one machine. An example of this is a machine for cutting sticks into square blocks, each having a bored and tapped hole part way through its center. Blocks of this kind are used as blanks for square knobs, such as are used on mission furniture, and the process is illustrated in Fig. 3. The machine for doing the work is shown in Fig. 4.

Stock coming to the machine is in the form of sticks planed on both sides and ripped to uniform width. The operator starts a stick through the machine on edge, that is, with the planed sides vertical, after which the piece is carried through the machine by means of the feed mechanism.

Three tools are mounted on a carriage which oscillates at right angles to the direction of the stick, a drill, a tap, and a circular saw, all in line. The feed first pushes the stock so that the end is opposite the drill and remains motionless while the carriage moves in and the drill bores the hole. After the carriage has moved back from the work, the stock is indexed automatically, bringing the hole which has just been bored opposite the tap and presenting a new section to the drill. On the following inward movement of the carriage, the first hole is tapped, while a new one is bored. The last operation of the series consists of cutting off the block with the saw and discharging it into a receptacle underneath. Once the series of operations is started, it is automatic and continuous, a block being drilled, tapped, and cut off at each stroke of the carriage.

On account of the tapping operation, the carriage must move in and out at a speed which will allow the tap to cut a clean thread and the tap must be reversed when it reaches the bottom of the hole. This is accomplished by feeding the carriage back and forth with a reversing screw mounted on the same shaft with the tap. Power is supplied from a countershaft by means of belts.

It is conceivable that each of the operations performed by the machine just described might be done as rapidly by means of simple machines operated by hand. However, much greater production is possible per operator when the three tools are combined in one mechanism.

### ROSETTE-CUTTING MACHINE

Automatic machinery is often thought of merely as a means of speeding up production. However, it may sometimes be used primarily to turn out work of a higher quality than hand

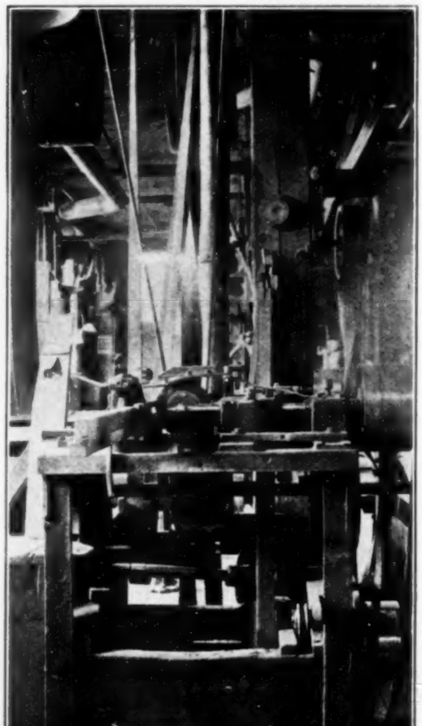

FIG. 4 SQUARE-KNOB MACHINE

methods, although it should be mentioned that production is very likely to be increased incidentally. A machine the main purpose of which is to benefit quality is the rosette-cutting machine. Its function is to cut a rosette in the face of a stick of lumber, a subsequent process releasing the rosette from the stick. The piece to be produced is shown in Fig. 5, and the machine in Fig. 6.

The machine uses as a foundation a standard high-speed

shaper, which has been changed into a special-purpose machine by the addition of special attachments. The top of the spindle has been cut off and threaded to receive a chuck for holding rosette knives. The standard screw mechanism for raising and lowering the spindle has been removed and a cam and pedal have been mounted underneath. The pedal raises the spindle for purposes of trial during the set-up, whereas the cam gives it an oscillating movement during the production period. The rotating knives are thus raised and lowered through a hole in the table, over which is placed the stock to be cut. A shoe mounted above the hole presses the stock down tightly against the table while the knives cut the stock from below.

Attached to the shaft operating the cam which raises and lowers the spindle, and timed with it, is another cam which controls the stock-clamping shoe just described. A feed mechanism is also operated from this same shaft by means of bevel gears and universal joints and indexes the stock forward between cuts. One stick is fed into the machine after another, the mechanism pushing them under the shoe, where they are clamped and cut as the spindle rises and are pushed along the diameter of the cut between strokes. The sticks are supplied to the machine in random lengths and the operator has time not only to feed the machine, but to saw out knots and other imperfections in the lumber with a handsaw before starting the sticks through the machine.

The outstanding feature of the rosette-cutting machine is the fact that the rise of the revolving knives into the wood is controlled mechanically and therefore accurately. The same operations could be performed on a manually operated machine with about the same speed, but it would be practically impossible to find an operator who could make all the strokes in exactly the same way, neither burning the wood by pushing the revolving knives into it too slowly, nor tearing it out by too rapid a cut.

### Economic Principles Involved

As stated before, the machines just described have been taken as types. They are not models of machine design nor of workmanship, having been built out of materials at hand by a factory

Fig. 5 Cross-Section of Rosettes Cut in Stick

millwright. However, they illustrate some of the principles involved in the design of automatic woodworking machinery as well as the fact that standard machines may be converted into single-purpose automatic machines by the addition of special attachments.

The rosette-cutting machine is built to meet requirements which do not usually have to be met by the standard automatic machines generally shown in manufacturers' catalogs. It must be able to do satisfactory work with all the ordinary kinds of cabinet woods, regardless of grain and texture. Clothes pins, spools, dowels, and most of the small parts for which standard machinery is made can be manufactured out of any wood which happens to combine strength, cheapness, and workability. The rosette-cutting machine not only has a larger variety of materials to deal with, but must turn out a product which is much smoother in finish than articles of a more practical nature.

Another factor present in the design of the machinery which has been described is the relatively short duration of the production period after the machine has been set up. Ten or twelve hours on one pattern is a high figure and one or two hours per set-up represents more nearly the average. For this reason, it is often necessary to sacrifice speed in production in the interests of rapid set-up.

In the opinion of the authors, there are a number of applications for automatic machinery in the woodworking industries which have not been developed. However, they believe that most of these applications are so isolated that the solutions are special machines for special operations rather than attempts on the part of the machinery manufacturers to turn out vastly increased lines of standard automatic machines. The most logical manner in which to develop an automatic machine is

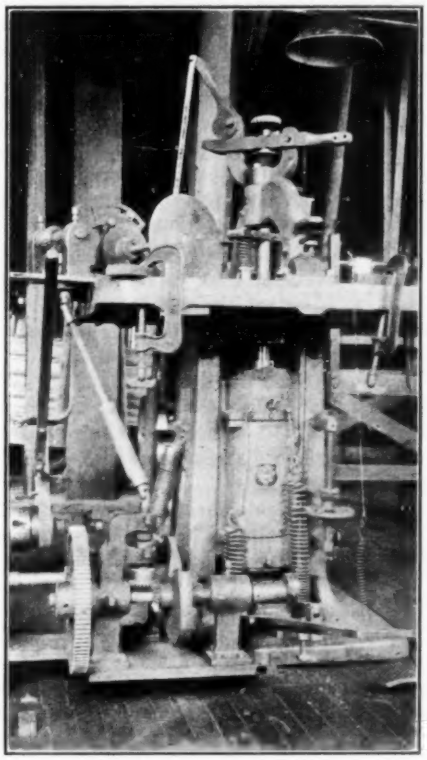

Fig. 6 Rosette-Cutting Machine

often found to be the application of special attachments to a standard machine.

Unless a comparatively large number of special machines are to be built, the cost of special patterns and the machining of special castings in small lots is unduly expensive if it is possible to adopt a standard machine for the purpose at hand.

When choosing the type of machine that will best perform a certain operation or group of operations, every method of working in wood should be considered. For instance, a lathe is not necessarily the best machine for producing a turning. A modified shaper may be able to handle the work much more efficiently, as in the case of the rosette-cutting machine. Among the less common processes of working in wood that should be taken into consideration are embossing with hot dies and shearing with cold dies somewhat similar to those used on metal punch presses.

After the type of machine has been decided upon, the machine designer must weigh ease of set-up against the number of pieces the machine is to produce per hour after production starts. Due to the rapidity with which wood may be worked, the set-up time problem assumes larger proportions than in the case of machinery for working harder materials.

The rosette-cutting shaper just described may be compared with a type of machine which is sometimes used for the manufacture of rosettes, consisting fundamentally of two cutting heads and a splitting saw. The heads are mounted opposite each other and oscillate back and forth on either side of the stock,

approaching and receding from each other so that they cut rosettes into both sides of a stick that is fed on edge between them. The stick then passes through the saw, which cuts out the center of the stock and allows the rosettes to drop out on both sides.

A machine of this type is obviously theoretically capable of turning out more work per hour than the modified shaper, inasmuch as two cuts are made per stroke instead of one. It is excellently adapted for long runs at one set-up.

In the case of shorter runs per set-up—for instance, one thousand or twenty-five hundred pieces of a pattern—the authors consider the simpler automatic machine to be preferable. When the running time per job is in the neighborhood of an hour, a difference of ten or fifteen minutes in the set-up time is very important, and the time saved in setting up a simple machine may often overbalance the increased production of a more complicated mechanism. The authors do not wish to disparage complicated machines, but merely to point out that set-up time should be considered as well as production.

Another factor to be considered in the design of automatic machinery is the quality of work to be produced. Increased production can often be achieved at the expense of quality. However, as a general principle, automatic machinery is more likely to turn out work of a high quality than hand methods. Mechanical feeds can be so designed as to move rapidly when no cutting is being done and to slow down at the proper instant to give a smooth finish. The manual skill of an experienced workman may often be built into a machine whose operator is to be merely an unskilled attendant.

In the consideration of automatic machinery, attention must be given to the economic side. The machine with the greatest capacity is not necessarily a good investment unless there is enough work at hand to keep it busy a large portion of the time. The cost of the machine must always be balanced against the savings it will make in labor, throw-outs, etc., and the possibility of not being able to keep the machine busy must be borne in mind. This self-evident condition is sometimes overlooked by enthusiastic machine designers and often by enthusiastic machinery salesmen.

The spectacular characteristic of automatic machinery is its increased capacity over hand methods. As has been explained in this paper, increased capacity may be achieved either by performing one operation more times per minute or by performing several operations at once, or by both methods. Even where the actual cutting operation cannot be speeded up, a mechanism can often be built to move the stock more rapidly between strokes and to avoid lost motions likely to occur when hand feeds are used.

Often when no attempt is made to turn out more work than could be produced by a good operator using hand methods, surprising increases in production may result from automatic methods. When the rosette-cutting shaper, described in this paper, was first put into operation, the feed mechanism was adjusted to give the same number of strokes per minute as were made by an experienced operator on a foot-pedal machine. To the surprise of every one, the output of the machine per day was found to be about twice that of the older machine. An analysis of conditions revealed a number of reasons for this:

In the first place, the automatic machine made the same number of strokes per minute at four-thirty in the afternoon as at seven-thirty in the morning. There was no human fatigue to contend with. Furthermore, not having to concentrate on mere mechanical movements of his arms and legs, the operator found time to inspect the stock as he fed it into the machine and to saw out defective parts, thereby reducing the number of throw-outs leaving the machine. A third reason for the increased output is the fact that the automatic machine produces more pieces per sharpening of the knives, and consequently there is less time lost in keeping the knives in shape. Due partly to the fact that the operator can cut out the knots from the stock before they reach the knives, and partly to the fact that the knives are always fed into the stock uniformly, they stand up appreciably longer on the automatic machine. The authors feel that some increase in production is almost sure to result from a change from hand to automatic methods, even when it is not the primary consideration in making the change.

## Discussion

Carroll A. Ross.[3] We have built some automatic machines, and we find generally that in every operation there is one limiting operation. For instance, on the rosette-cutting machine the speed at which the knife can approach the work is probably the limiting factor. The rest of the operation—the moving of the stock, which is so very light that it can be moved with great rapidity—can be accomplished so that the cutting tool can actually be cutting a large part of the time.

Thomas D. Perry.[4] Frank Gilbreth said to me some years ago, as he went through some of the factories in Grand Rapids, that he felt there was a tremendous need to apply automatic methods to repetitive woodworking operations. It was a field very greatly neglected, he felt. He was referring not only to the making of small parts by automatic machinery, but to the automatic feeds of various types that could be and some of which since have been applied to various woodworking-machine operations.

Monte B. Gathman.[5] Mr. Perry probably does not realize how much automatic machinery there is in this country. Many of the larger concerns maintain departments for the development of automatic machinery; other progressive concerns have these ideas developed by small machine shops over the country. The authors show three or four machines they have developed; Mr. Ross has developed others; Fisher Body Corporation has developed many automatic machines. These machines as a rule cover specific operations, not applicable for general use, but the total would reach a sizable figure.

An automatic shaper has been designed that will do the work of two double-spindle shapers; it takes up less floor space than the two machines it replaces and takes the danger away from the operator and much of the hard work.

David Turcott.[6] We have had some requests to build automatic machinery. Automatic machinery is undoubtedly coming, and we intend to follow the demand in developing it. So far, the demand has been only for special automatic tools for which there is a very limited market. The demand for automatic machinery will increase rapidly as soon as manufacturers of wood products are forced by competition to use it.

M. Everett Dick.[7] We once built an automatic shaper for making brush handles. It had six spindles with automatic feed and seven motors—two to make the side of the handle, two spindles to make the inside curve, two to make the outside curve, and another motor for the feed. This is what we are up against

[6] Yates-American Machine Company, Beloit, Wisc. Assoc-Mem. A.S.M.E.

[7] Buss Machine Works, Holland, Mich.

in the manufacturing of automatic machinery. What are the prospects of getting an order for a second machine?

We have made a great many automatic machines successfully, and I am a believer in making woodworking machines as fully automatic as possible, removing the human element absolutely, because it is going to help to standardize the product.

That machine for automatically making brush handles among other things eliminates many different styles of brush handles. With more automatic machines, fewer varieties will be made, but more of one particular design.

Manufacturers of woodworking machinery want the users of it to explain their problems before the machine is bought so that the designing may be worked out together.

M. D. Baldwin.[8] Those in the wood industry probably have a considerably exaggerated idea of the business and the importance financially of the machinery builders. Exclusive of the sawmill manufacturers there has not been a year since statistics have been available, and that covers a period since 1918, in which the manufacturers of woodworking machinery have done a gross volume of business exceeding $20,500,000, while the total yearly business of the wood industries is about $4,000,000,000. Thus it is evident that the manufacturers of woodworking machinery have little available capital and little interest in attacking these specialized problems of the woodworking industry.

There are any number of factories working in wood which have an individual volume in excess of the total volume of the manufacturers of woodworking machinery. Consequently, we are able only to approach this building of special machines as agents of those who have foresight and are willing to attack problems and pay a return commensurate with the effort put on the first machine.

I recall a machine built for the General Electric Company. They were willing to pay the expense necessary to develop a wedge cutter. Subsequently they ordered another. We are going to make money on the second machine. The General Electric Company will pay for the machine in four to six months from the savings it effects; the only profit we can make is what we may make out of the one or two machines that can be sold.

The wood industries have a tremendous volume of business. The manufacturers of machinery do not turn over their capital invested more than one and a half times a year. This is an indication of the amount of investment necessary to produce that $20,500,000. This is an angle which few have considered. I bring it up in no sense of complaint. We are proud of our position. We have helped the wood industries to make progress, and you in turn have given us money to live on. Nevertheless, it takes funds to develop new and special machines. We are willing and glad to do it, and some of the big firms have acted handsomely in helping out on these special problems. There are many smaller firms that need the same sort of automatic equipment, but that are not willing to carry on far enough to put it across.

Armen S. Kurkjian.[9] Nothing has ever been accomplished without the cooperation of the user and the manufacturer. It is the user who sees certain needs in his particular field and puts himself immediately in touch with the manufacturer who may assist him in the production of a machine to do that particular work. He soon finds that cooperation gets him very good results.

As a concrete example, Mr. Gathman came to Grand Rapids one day with some problems in his mind. He outlined certain things that they were doing and that should be changed; things that ought to be done automatically so as to save time. The result was that we developed a machine, now in operation, that with one man can do the work formerly done by four machines with one man each, or four men. That is a ratio of one to four in direct labor saving, and of course the floor space saving also is considerable.

Mr. Baldwin mentioned the instance of the wedge-cutting machine for the General Electric Company. That again was the result of cooperation—of studying the problem and meeting the need.

The automatic shaper that was developed was without a question the result of cooperation. The automatic rosette-cutting machine was the direct result of cooperation.

Cooperation between the fabricators of wooden parts and the woodworking-machinery manufacturers will assist both 100 per cent, and the net result will be that the fabricators of wood will get the greater good out of it because the returns will be continuous to them.

Many of the larger woodworking companies have their own experimental research department, which does evolve certain machines for their particular needs. What will take them about two years to design and to put in actual practice will probably take not to exceed three months for the well-organized woodworking-machinery manufacturer who already has a corps of engineers well trained for such work.

### Authors' Closure

The representatives of the machinery manufacturers who have discussed the paper confirm the opinion of the authors that the building of special automatic machinery is not a very profitable business for the machine builders. However, there seems to be a concensus of opinion that such machines may often be a very good investment for the user of the machine, and several of the machinery representatives have suggested that the users of machinery should place such problems before them.

While this procedure would undoubtedly accomplish much, still it might also be to the benefit of the machinery manufacturers to devote some effort to educating users to the value of automatic machinery in general. In other words, since the user must ultimately bear the cost of developing special machinery, it might pay the machine manufacturer to make his customers see how much to their advantage such special machinery would be.

It seems possible that the cost of special machinery might be reduced somewhat below the prices usually quoted by more often working out feed attachments, etc., rather than by building special equipment from the ground up.

Furthermore, in view of the number of different electrical frequencies above 60 cycles now being used in connection with woodworking machinery, the cost of a frequency changer to be used with a special machine is often an item of considerable expense. A number of different makes of routers are operated successfully on 60-cycle current, using belts or friction drives to obtain speeds as high as 20,000 r.p.m. Since a special machine is always rather high in first cost, anything that can be done to make it less expensive should encourage its development, and there are surely some occasions on which the frequency changer might be dispensed with for the sake of lower first cost. The savings made possible by the use of an automatic machine will usually justify its use even though its design is not as finished and its appearance not as trim as those of a standard general-purpose machine.

# Obtaining the Maximum Fuel Value From Wood Waste

## Amount of Lumber Wasted in Average Woodworking Establishment—Arrangement of Boiler Plant for Efficient Utilization of Wood as Fuel—Installations for Special Conditions—Avoidance of Gas Explosions in Furnaces and Shavings Pipes

By E. WINHOLT,[1] MOLINE, ILL.

IN THE lumber industry there is a considerable amount of waste from the time the lumber is out on the ground until it leaves the factory as a finished product. It would be hard to estimate just how large a percentage the waste is, but it may safely be assumed that not less than 50 per cent of the lumber is waste in one form or another.

In the sawmill operations, where the logs are turned into dimension lumber, the waste consists mainly of trimmings, ends, bark, and sawdust. All of these leave the sawmill and are generally used for fill in low lands, except a very small percentage which is burned under the mill boilers in the form of sawdust.

Sawmills are generally located far from any market where such waste could be sold, and as it contains a considerable amount of moisture, it would not pay to ship it. There is therefore not much that can be done in salvaging such waste.

After the lumber has been shipped to the sawmills and the lumber yards either operated in connection with wholesale or retail business, or located and used for storage for manufacturing purposes of different kinds, there is again a large waste, but this time it is near a market and the lumber is in a far drier state than obtained at the sawmill.

### Waste of Lumber in Average Factory About 25 Per Cent

In factories such as planing mills, woodworking establishments, or other enterprises where the lumber and rough stock are worked into the finished product, the waste amounts to not less than 25 per cent of the total lumber. In these cases the sawdust, shavings, and often the trimmings and the mill wood are burned under the boilers to supply power for the industry, and some of their fuel value is obtained in this manner. Where more refuse is available than can be used in this way, it is sold in a general market to be used for kindling wood, mainly for household purposes.

It may be stated in passing that a wagon factory manufacturing a regular line of farm wagons found that for a finished wagon weighing 1200 lb. there was produced from the lumber used for each wagon 240 lb. of shavings. This information was arrived at by two different methods:

*a* Weighing the shavings delivered to the boiler room when factory was working on 100 wagons per day.

*b* Checking the dimensions of each piece of lumber which was used in the manufacture of one wagon and again checking the dimensions of the finished part.

It is evident that by utilizing the wood refuse in an efficient manner, a decrease in the cost of the fuel is effected and a corresponding amount of coal is left in the ground, in which way natural resources are conserved. Such wood should therefore so be burned that the greatest possible amount of heat is obtained from a given quantity. This, however, is not the case. Generally, it is considered that just because the wood refuse must be disposed of and does not cost the factory anything, the efficiency of its combustion is of no importance.

However, there are today plants where planing mills and sash-and-door works are now supplying their entire requirements for heat, light, and power from sawdust and at the same time selling the mill wood and trimmings for domestic use. In such cases the installation for obtaining this result has proved an excellent investment. What has been done in some of these factories can be accomplished in practically all of them, provided the management will take steps to have the installation brought up to date, and will utilize the best talent and mechanical equipment obtainable.

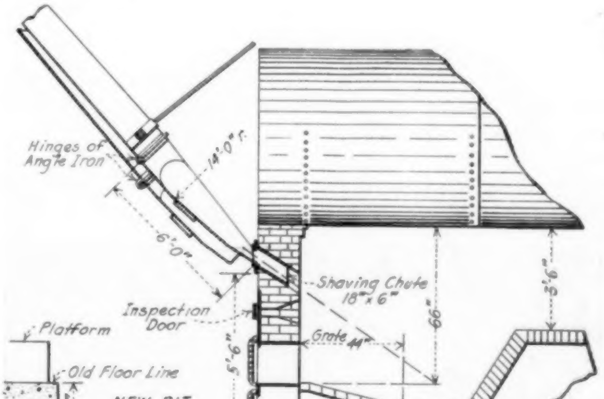

Fig. 1 150-Hp. Horizontal Return-Tubular Boiler Arranged for Burning Shavings

There are a large number of places where wood refuse is burned in an inefficient manner, and where coal has to be supplied in addition. Where such is the case, the coal is generally hand fired at the same time the shavings are admitted from shavings systems overhead, or possibly also fired by hand. There is no question that shavings mixed with coal screenings make a good fuel which burns readily, but sight is entirely lost of the fact that the furnace and the firing methods which contribute to high efficiency on the wood are not at all suitable for the burning of coal, and vice versa.

### Arrangement of Boiler Plant for Efficient Utilization of Wood as Fuel

It has been proved by actual tests that where more than one boiler is operated it is far more desirable to operate one or more of them on shavings, and should the amount of steam produced be insufficient, then to operate one or more on coal, thereby operating both of the two groups at maximum efficiency.

In burning any kind of fuel under a steam boiler, the purpose is to produce the largest amount of steam from a given quantity

[1] Deere & Co.

Presented at a meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., November 26 and 27, 1928. For discussion see page 33.

of fuel. The ratio between the two is generally called the rate of evaporation, and may range from 1 to 5 lb. for shavings and from 4 to 9 lb. for coal. The more pounds of steam produced with a pound of fuel, the higher the efficiency.

In a test carried out in a plant where for a long period of years both shavings and coal were burned together, it was found that less than 2 lb. of steam was produced per pound of shavings; whereas when the shavings were burned alone in boilers suitable for the purpose, approximately 5 lb. of steam was produced from 1 lb. of dry shavings. This test indicated that for a long period of years a great waste had been taking place in the combustion of the wood and refuse, which had to be made up by the burning of coal in order to take care of the demand for steam.

In arranging a steam boiler for the efficient utilization of wood as fuel, the prime requirement is furnace volume. A good ratio is one cubic foot of furnace volume for each developed horsepower. Or, in other words, if a 500-hp. boiler is installed and it is desired to obtain 1000 hp. from it, the furnace volume should be not less than 1000 cu. ft.

It has often been stated that wood refuse such as shavings should be dropped by gravity on the grate, and that all the air required should be admitted through the grate. This, however, does not hold in the case of dry wood shavings or refuse, as here the proposition is mainly one of surface combustion. Only a very limited amount of grate surface is required, but air should be admitted over the fire either along with the shavings or separately.

The simplest method is to introduce the shavings through a spout from the cyclone leading through the front of the furnace wall, and to use a Dutch oven setting where a flat suspended brick arch is hung over the furnace and reflects the heat of combustion down upon the shavings in the furnace. Following this arrangement, the fine shavings are burned in suspension when entering the hot furnace in a manner very similar to that employed in the combustion of pulverized coal. The shavings which do not burn in suspension are carried by the air and their momentum down on to the grate, where a small pile is formed which is burning around its edges and on the surface due to the air introduced with the shavings.

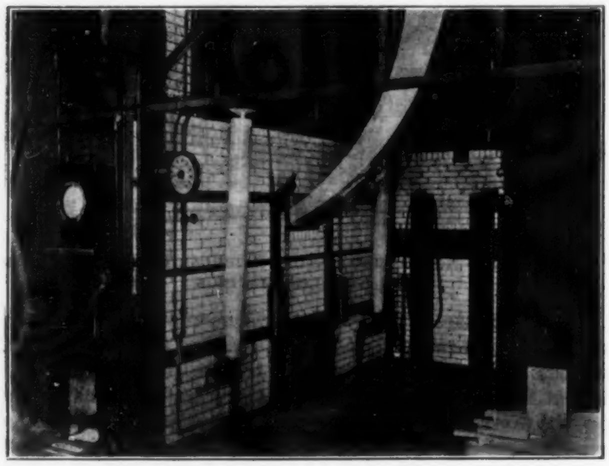

Fig. 2 Front of 344-Hp. B. & W. Water-Tube Boiler for Burning Shavings, Refuse, and Scrap Wood

While a fairly good draft is required to burn coal because of the thickness and density of the fuel bed, the opposite is the case with dry wood shavings. Under the conditions above stated, boilers operate very satisfactorily with drafts over the fire ranging from 0.05 to 0.20 in. The complete combustion takes place in the furnace and in the front tube section, and practically no combustible is carried over into the rear pass.

A boiler operating in this manner may run for six to twelve months without cleaning out the ashes from the rear pass; whereas, when shavings were burned together with coal, the half-burned wood particles would fill the rear end of the boiler and the smokestack in a very short time.

Wood refuse is a very desirable fuel when handled in the proper manner and is to be preferred in all cases over coal. It makes a very hot fire and will start a boiler up from cold in a very short time; also, when operation is to be discontinued, the shavings in the boiler may be burned out in a few minutes and the boiler may be left safely until operation is again commenced.

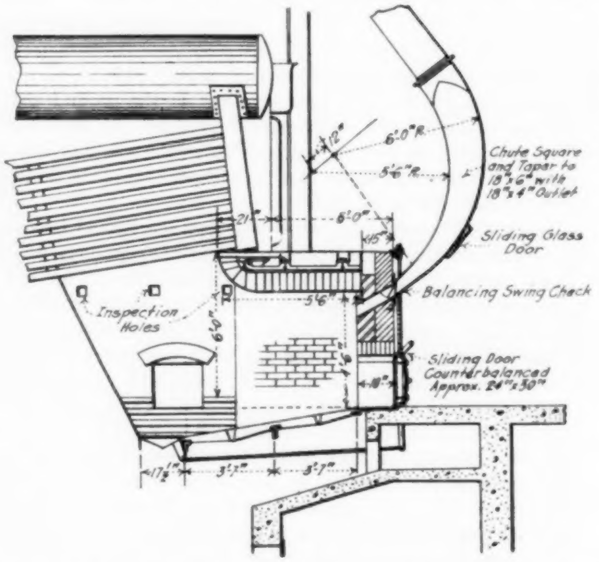

Fig. 3 250-Hp. Water-Tube Boiler Rebuilt With Dutch Oven for Burning Shavings

Besides wood shavings and refuse from the wood shops, there is a large amount of scrap wood, boxes, barrels, kegs, etc., to be disposed of in the average industrial establishment every day, and in place of loading all this on a wagon and hauling it to a convenient dumping place, it is good economy to burn it under boilers equipped for that purpose and for the burning of shavings. In spite of this, however, many industrial establishments maintain a continuous bonfire in their back yard and at the same time pay a high price for the fuel they burn under the boilers.

### Installations for Special Conditions

Fig. 1 shows a 72-in. × 18-ft. horizontal return-tubular boiler arranged for burning shavings from the shaving system and scrap wood by hand firing. The grate is a single herringbone-type bar 44 in. long and the width of furnace at the grate line is 5 ft., thus making a total grate surface of 18 sq. ft. The distance from the grate to the shell of the boiler is 66 in. Between the rear end of the grate bar and the bridgewall is a level ledge 2 ft. in length to provide for the accumulation of shavings and form a pile at all times covering the rear of the grates solid. This pile of shavings acts as a heat-storage or heat-equalization medium. The flow of the shavings is directed on to this storage arrangement. This boiler, which is rated at 150 hp. will without difficulty develop 200 hp. No spreading, raking, or other disturbance of the fuel bed is permissible.

Fig. 2 shows the front of a 344-hp. B. & W. water-tube boiler.

The setting height, measuring from the floor line to the bottom of the front headers, is 8 ft. This boiler has no Dutch oven and only 44 in. length of grate bar, with a width of 6 ft. at the grate line; the furnace width is 8 ft. Between the rear end of the grates and the bridgewall is placed a double dumping grate 27 in. long, thus making a total grate surface of 28 sq. ft. and a total furnace volume of 455 cu. ft. The grate is placed at the floor line and slopes toward the rear. A regulated door to admit air from the boiler-room tunnel to the under side of the grates is provided.

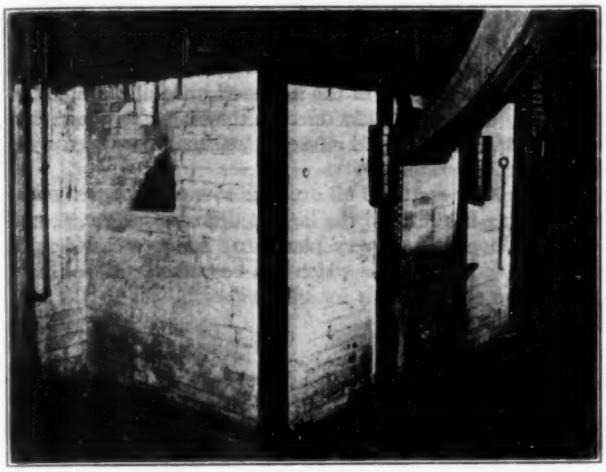

FIG. 4 VIEW OF FRONT OF BOILER SHOWN IN FIG. 3

The front has a 6 × 18-in. cast-iron 60-deg. chute with a balanced check valve for admission of the shavings and a 24 × 30-in. counterbalanced sliding door for the firing of refuse and scrap wood. On each side of the front door is placed an oil burner which is used when there is a deficiency of wood or shavings.

This boiler will produce 700 hp., in which case additional air must be admitted under the front door in order to eliminate heavy smoke. A flow meter and draft gage is placed in a prominent position on the front left corner and a $CO_2$ recorder on the side.

Figs. 3 and 4 show a 250-hp. boiler which was rebuilt from a stoker-fired setting, retaining, however, its low (5 ft. 6 in.) setting height. A Dutch oven was placed in front of the old setting and furnished with a flat suspended arch, shaving chute, and front door, the same arrangement as used under the previous boiler.

The grates in this furnace are 88 in. long and with a dump grate to the rear; the total grate surface is 47 sq. ft. This boiler has developed over 500 boiler hp.

Figs. 5 and 6 show a 363-hp. boiler which is an enlargement and improvement over the boiler shown in Figs. 3 and 4. The fact is that the 250-hp. boiler which was rebuilt in 1921 saved enough money on fuel cost to purchase and install this new 363-hp. boiler, and after its completion the 250-hp. boiler was scrapped because of the limited pressure allowed by the boiler insurance policy.

It is a new installation with a setting height of 12 ft. The grate length is 88 in. with a dump grate to the rear. There is an oil burner on each side of the front sliding door. The grate slopes 2 ft. downward; the distance to the Dutch oven is 10 ft., and the grate area is 50 sq. ft. The total furnace volume is 1030 cu. ft. This boiler has developed 800 hp. and should be capable of delivering 1000 hp. when sufficient fuel is available. This is a very successful setting for shavings, scrap, and factory refuse.

These two latter boilers have a peculiarity well worth mentioning and which is contrary to what would naturally be assumed. When this type of setting is hot and the rear of the grate has an accumulation of combustible on it with additional fuel entering from the shaving chute, the flame under the Dutch oven rolls forward under the arch and toward the front of the Dutch-oven wall. At this point the air and shavings from the chute strike the current, and force it downward and toward the shavings pile at the bridgewall.

At such times, when no fuel is fed to the boiler, the air emerging from the shavings chute is burning into the storage pile, which is evidenced by a hole in the pile in a straight line with the direction of the chute.

## AVOIDANCE OF GAS EXPLOSIONS IN FURNACES AND SHAVINGS PIPES

It may be asked how it is possible to operate the previously illustrated boiler settings with a low draft regulated by the damper to the smokestack and at the same time avoid dust or gas explosions inside the furnace or in the shavings pipes and cyclone.

The greatest danger is present in the morning or at other times when the boiler is fired up after having been down for several hours. In such case the boiler is filled with dry shavings or sawdust and the heat from the brickwork raises the temperature of the fuel to a point where wood gas is distilled off faster than the smokestack can carry it away, and it is merely a question of time until this gas ignites and produces an explosion which may wreck the entire boiler setting. Such an explosion took place when the above-mentioned horizontal return tubular boilers were first rebuilt and was caused by the carelessness of the fireman, but this was the only explosion he ever had. To prevent their occurrence, it is only necessary to light the fire and let the gases burn as they are given off from the fuel.

FIG. 5 363-HP. BOILER WHICH IS AN ENLARGEMENT AND IMPROVEMENT OVER THE ONE SHOWN IN FIGS. 3 AND 4

Backfires from the firebox through the shavings pipe and into the cyclone have occurred and have been the cause of serious

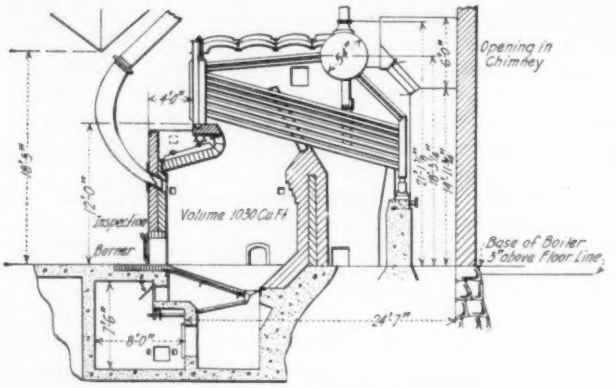

Fig. 6 View of Front of Boiler Shown in Fig. 5

accidents. To eliminate this danger, a cast-iron chute is placed in the front wall of the boiler and fitted with a cast-iron balanced check damper which, as long as pressure is carried in the cyclone, remains partly open and passes the stream of shavings while it retains the greater part of the air. Should the pressure in the firebox exceed that in the shavings chute or should the blower or fan which feeds the cyclone cease to function, this check valve will automatically close.

Serious accidents have taken place caused by either of the above causes, and it is well worth while to take the proper precautions and properly instruct the operating force to eliminate any chance of their occurring.

The proper utilization of wood as fuel has been neglected for many years, but because of the increased price of coal and the competition between manufacturers in the same line, the matter of proper utilization of wood refuse for fuel has of late been given very great consideration.

There are now scattered all over the country factories where wood burning has reached the highest degree of efficiency, and it is to be hoped that every plant that has any considerable amount of wood or refuse which can be burned, will see fit to adopt means and methods for utilizing such fuel to the best advantage.

# Wood-Burning Furnaces WDI-50-16B

By BURRITT A. PARKS,[1] GRAND RAPIDS, MICH.

*After pointing out the value of wood refuse as fuel for boilers in woodworking plants, the author discusses the nature of wood refuse and the heating value of various species of wood. He then considers the conditions which are necessary for the efficient combustion of wood refuse, and sets forth the principal requirements in the case of kiln-dried wood, after which he describes various furnace designs which have been successfully employed. He closes with an appeal for better engineering in the design and operation of woodworking plants.*

MUCH has been written of late regarding the proper design of wood-refuse-burning furnaces and the efficient combustion of wood refuse as a fuel. While the author does not presume to add greatly to the sum total of knowledge on these subjects, he nevertheless believes that a résumé of recent developments, together with the results of some of the experiences of his company, may not come amiss in furthering the discussion of these important problems.

The increased cost of coal during and following the World War, together with the propaganda carried on by various Government agencies and engineering societies in the interest of conservation of fuel, have combined to open the eyes of power-plant owners and operators to the possibility of reducing fuel consumption and therefore cutting operating costs. Much has been accomplished along this line, but judging from appearances in many manufacturing plants, there is still much work to do.

The managements of many woodworking plants have in the past apparently labored under the misapprehension that the wood refuse resulting from their manufacturing operations was a waste product pure and simple and that its disposal was the primary consideration, economy in its use being of little or no importance.

Intelligent thought will convince one that this is the wrong point of view, particularly for a plant where the wood refuse is insufficient to supply the demand for fuel, for, as will be pointed out later, every 2 to $2^1/_4$ lb. of wood efficiently burned in the furnace results in the saving of 1 lb. of coal, and this gives a real dollars-and-cents value to the refuse viewpoint.

In order to accomplish the maximum in fuel savings, certain conditions must be met, such as proper furnace design, suitable means for feeding the wood refuse to the furnace, and intelligent operation. Incomplete combustion and excessive temperature of the stack gases are the two most potent causes of the inefficient use of fuel. The proper control of these factors is not a matter of guesswork; neither is it entirely a question of experienced observation. Data must be supplied to the fireman so that he may definitely control the drafts, air supply, and fuel supply in accordance with the load conditions. To this end certain instruments are necessary, such as steam-flow meters, draft gages, recording thermometers, and flue-gas analyzers. There are many who will question the advisability of making the investment in such instruments. The author's only answer to this is that the increased efficiency resulting from positive control of combustion conditions will pay a surprising return on the investment—and this statement is not based on idle generalities but is the result of observation and experience in plants under his charge.

### Value of Wood Refuse

The amount of wood refuse available as fuel in a woodworking plant will, of course, vary with the nature of the product. In most furniture-manufacturing plants, for example, the waste will vary from 25 to 40 per cent of the lumber cut; 30 per cent would probably be a conservative average. This means that for every 1000 ft. b.m. of lumber cut, averaging about 3 lb. per ft. b.m., there will be 1000 lb. of refuse sent to the boiler room, which, when efficiently used, will replace 500 lb. of coal.

Very frequently manufacturers will sell their cuttings for domestic uses, and they should not lose sight of the fact that every load of cuttings sold, in most cases at least, must be replaced by the equivalent fuel value in coal. This means that the manufacturer should dispose of the cuttings at a price that will at least allow him to buy an equivalent fuel value in coal for the

[1] Consulting Engineer, Byron E. Parks & Son. Mem. A.S.M.E.

Presented at the National Meeting of the A.S.M.E. Wood Industries Division, Grand Rapids, Mich., Nov. 26 and 27, 1928.

same money. A survey was recently made at a woodworking plant where the cuttings had been sold for years at a price that would not purchase a fuel equivalent in coal. Manifestly this was a poor bargain for the manufacturer.

Due to the fact that most woodworking plants require steam throughout the year for lumber drying and other process work, it is necessary to operate a boiler plant throughout the year, irrespective of whether power is developed or not. Taken in conjunction with the fact that large quantities of wood refuse are available for fuel and that exhaust steam from engines is exactly as satisfactory a heating medium as low-pressure steam from the boilers, it may easily be shown that in over 90 per cent of the cases, woodworking plants cannot afford to purchase outside power at rates ordinarily in effect. The wood refuse available as fuel is the predominant factor affecting this situation, and it therefore behooves any woodworking plant purchasing power to make a careful survey of its steam and power demand, for in most cases there is an opportunity for effecting substantial reduction in the cost of these items.

### Nature of Wood Refuse

Before discussing the proper conditions for the efficient use of wood refuse as fuel and the design of wood-burning furnaces, it is essential to have an understanding of the nature of the fuel it is proposed to burn. The lumber industry has practically disappeared from this section of the country, and consequently this discussion will be confined to a consideration of the wood refuse ordinarily available in woodworking plants of this and similar communities. For the purpose of this paper only kiln-dried or thoroughly air-dried stock will be considered.

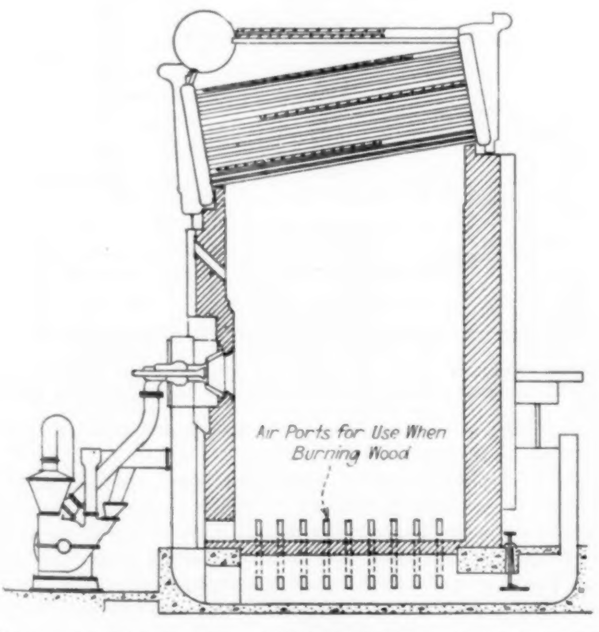

Fig. 1 Cross-Drum Type of Water-Tube Boiler With Boxlike Furnace for Burning Wood Refuse

It is generally assumed that the heating value per pound of dry wood is the same for all species, as the composition of dry wood is approximately as follows: carbon 49 per cent, oxygen 44 per cent, hydrogen 6 per cent, and ash 1 per cent. As a matter of fact, the different species contain varying amounts of resins, oils, and gums, so that the actual composition and heating value, as given by Gottlieb, is as follows:

| Kind of wood | C | H | N | O | Ash | B.t.u. per lb. |
|---|---|---|---|---|---|---|
| Oak | 50.16 | 6.02 | 0.09 | 43.36 | 0.37 | 8316 |
| Ash | 49.18 | 6.27 | 0.07 | 43.91 | 0.57 | 8480 |
| Elm | 48.99 | 6.20 | 0.06 | 44.25 | 0.50 | 8510 |
| Beech | 49.06 | 6.11 | 0.09 | 44.17 | 0.57 | 8591 |

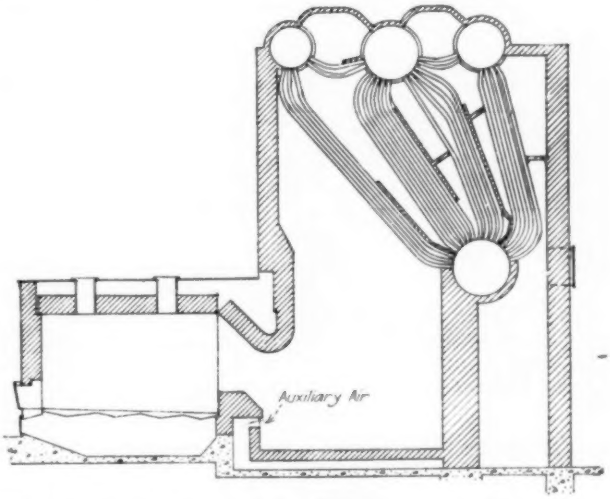

Fig. 2 Type of Furnace Found Successful in the Burning of Wet Hog Fuel

To show the variation in heating value of wood due to water content the following table, given by J. H. Hinman, is presented.

| Moisture, per cent | Available heat, B.t.u. per lb. |
|---|---|
| 10 | 7703 |
| 20 | 6705 |
| 30 | 5707 |
| 40 | 4710 |
| 50 | 3712 |
| 60 | 2715 |
| 70 | 1717 |

This table is based on a heating value of 8700 B.t.u. per pound of wood with an assumed flue-gas temperature of 560 deg. fahr. The available B.t.u. per pound of wood fuel indicates the net heating value after deducting the B.t.u. required to heat the moisture to the boiling point, evaporate it, and superheat it to the temperature of the flue-gas temperature, viz., 560 deg.

From an examination of the above tables it will be observed that the B.t.u. value of the common species of woods carrying about 5 per cent of moisture will be about 50 per cent of that of a good grade of bituminous coal. In other words, for comparative purposes it is conservative to assume that in most woodworking plants two pounds of wood refuse is equivalent in fuel value to one pound of bituminous coal.

In burning wood the volume of gases given off is much larger than for coal, and, as will be shown hereinafter, this fact has an important bearing on the design of boiler settings, breechings, chimneys, etc. The following table, as given by R. L. Beers,

| Moisture per cent | Efficiency, per cent | Wood per hp-hr. as fired, lb. | Flue gases per hp-hr., lb. | Cu. ft. per hp-hr., at 600 deg. | Ratio of gas volume, wood to coal |
|---|---|---|---|---|---|
| 0 | 70 | 6.00 | 61 | 1560 | 1.11 |
| 20 | 65 | 8.05 | 66 | 1715 | 1.22 |
| 40 | 57 | 12.25 | 80 | 2120 | 1.51 |
| 60 | 43 | 24.40 | 114 | 3150 | 2.24 |

indicates the approximate volume of flue gases, assuming a temperature of 600 deg. fahr.

### Conditions for Efficient Combustion of Wood Refuse

As has been pointed out above, the combustion of wood refuse results in the giving off of a large volume of gas. It therefore

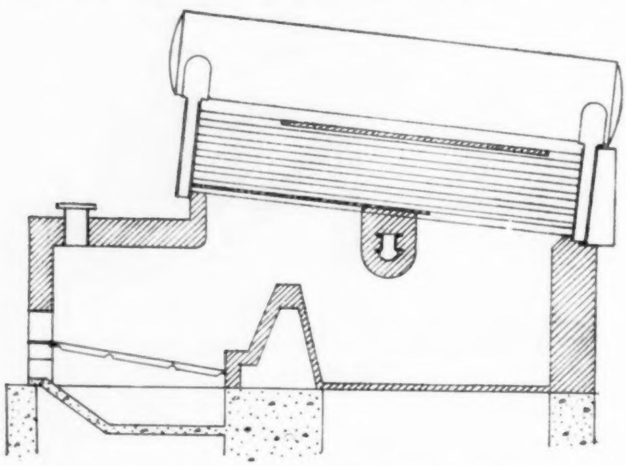

Fig. 3 Special Furnace Designed for Burning Both Wet and Dry Wood Refuse

requires a design of furnace different from that required for coal to obtain the best results.

The practice ordinarily in vogue for supplying fine refuse to the furnace is to either spout it directly from the separator or else use some special design of feeding mechanism conveying the refuse from a storage bin. In any event, a considerable portion of the sawdust and shavings is burned in suspension and the remainder drops in piles on the grate, when combustion takes place largely on the surface of the piles. Due to the impossibility of obtaining an adequate air supply through the fuel bed itself, air must be admitted above the fire. If there is a deficiency of air admitted above the grate, incomplete combustion will result, and in consequence heavy black smoke will be given off.

In general, the fuel bed should not be disturbed as combustion, which is taking place on the surface, will be interfered with.

One of the largest sources of loss in most plants results from the fact that fuel and air are not properly proportioned and supplied to the furnace in accordance with the load on the boiler. For this reason, automatic means for feeding the fuel to the furnace, as will be described hereinafter, should be employed in order that the highest efficiency in the use of the fuel will result. It has been conclusively demonstrated that the savings resulting from proper means of regulating the fuel supply will pay handsome returns on the investment required to accomplish this object.

Kiln-dried wood, sawdust, and shavings are burned to a great extent in suspension, and on account of the large volume of gas given off and the necessity of obtaining a thorough intermingling of the air with these gases a large combustion space is necessary. There is a tendency toward larger combustion spaces, and whereas 3 to 5 cu. ft. of space per rated horsepower was considered ample a few years past the author believes that 7 to 8 cu. ft.—or even more—per horsepower of rated boiler capacity will give better results.

In large boiler plants having a number of boilers installed, part of the settings may be designed to burn wood only and the remainder designed for coal. In most plants, however, the settings should be designed for a combination of coal and wood refuse so that no interference with operation will result from a stoppage of the wood supply. The method of coal firing to use depends somewhat on the size of the boiler unit and the ratio between the coal and wood refuse required to carry the load. Stokers and pulverized coal are coming into use rapidly, and have the advantage that automatic control will "cut in" the coal supply as the supply of wood refuse drops off.

In many ways unit pulverizers form the ideal scheme for feeding coal as they are more responsive than the stoker in taking care of variations in the wood supply.

Another advantage in using pulverized coal is that grates may be omitted entirely. As has been mentioned, refuse such as kiln-dried shavings and sawdust burns best on the surface of the piles, and consequently a plain brick bottom to the furnace answers every requirement. Air is admitted through small openings near the furnace bottom directed toward the piles. With this design hollow-wall furnace construction is advisable as

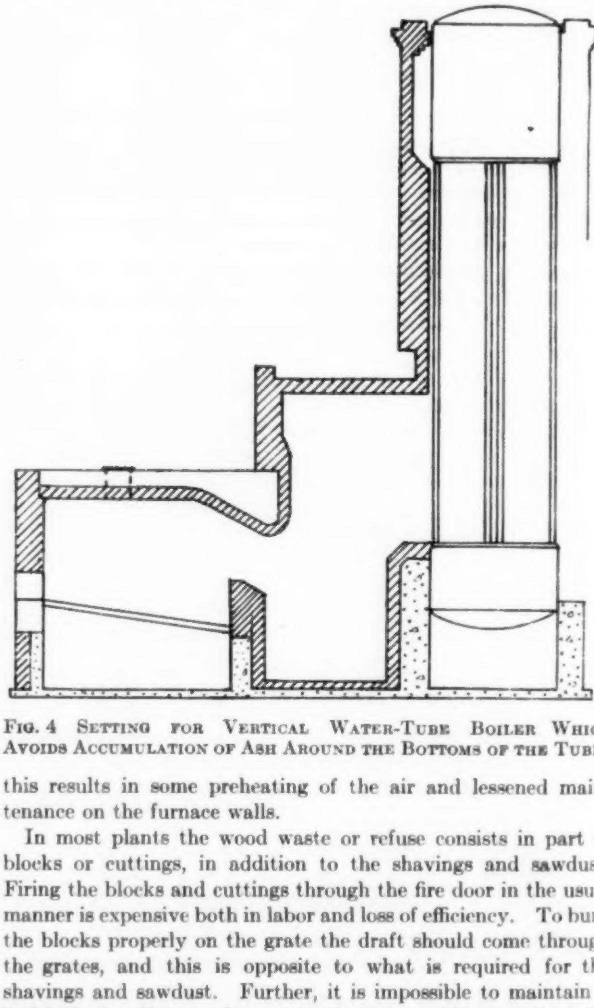

Fig. 4 Setting for Vertical Water-Tube Boiler Which Avoids Accumulation of Ash Around the Bottoms of the Tubes

this results in some preheating of the air and lessened maintenance on the furnace walls.

In most plants the wood waste or refuse consists in part of blocks or cuttings, in addition to the shavings and sawdust. Firing the blocks and cuttings through the fire door in the usual manner is expensive both in labor and loss of efficiency. To burn the blocks properly on the grate the draft should come through the grates, and this is opposite to what is required for the shavings and sawdust. Further, it is impossible to maintain a fuel bed of uniform resistance, and consequently control of the air supply is impossible.

There is only one answer to this condition, and that is to "hog" the blocks and cuttings. The "hogs" may be located at strategic points throughout the plant (resulting in a decrease in labor for trucking), and the hogged material delivered into the regular exhaust system.

In spite of the comparatively large power consumption and maintenance required for the "hog," tests have shown con-

clusively that in most cases the decrease in labor and increased efficiency in burning the hogged material will show savings that will pay a good return on the investment.

## Descriptions of Various Furnaces

The principal requirements for the efficient combustion of kiln-dried wood refuse may be summed up as follows:

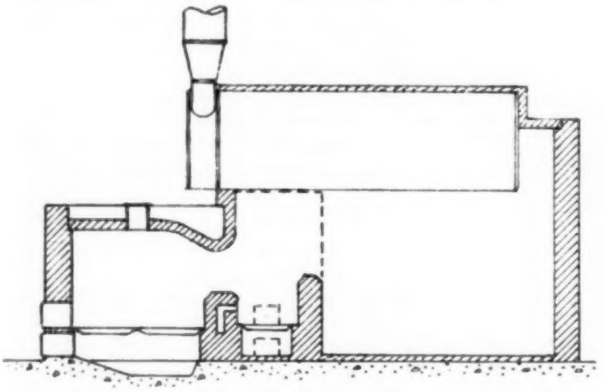

Fig. 5 Successful Type of Setting for Horizontal-Return Tubular Boiler

1 Ample combustion space to insure as complete combustion as possible before the hot gases come in contact with the water-heating surface
2 Means of feeding the wood refuse whereby the supply of refuse may be controlled in accordance with the load
3 Means for admitting the air supply to the furnace at the proper points and controlling it in synchronism with the fuel supply
4 Ample draft, but with means for controlling it, preferably automatically, so that the fine particles will not be unduly drawn over the bridge wall or into the gas passages of the boiler
5 Suitable means of firing coal as an auxiliary fuel, preferably using stokers or a powdered-coal installation, arranged with automatic control so that the auxiliary fuel will "cut in" as the supply of wood refuse drops off. Parenthetically it might be stated that oil fuel and natural gas make ideal auxiliary fuels, but on account of the cost or not being available, they are seldom used
6 Proper complement of instruments, such as steam-flow meter, $CO_2$ indicator, draft gages, thermometers, etc., so that the fireman may intelligently control the various elements of the installation to give the maximum possible efficiency at all times.

Keeping in mind these requirements, it may be of interest to examine a few typical furnace designs and see how these requirements are met.

Fig. 1 indicates a cross-drum type of water-tube boiler set over a large box-like furnace. A unit-type coal pulverizer is used to supply the auxiliary fuel. No grates are used, the bottom of the furnace being of brick. Wood refuse is spouted from a screw feeder (not shown) through the diagonal chute in the front wall. Air is admitted through the openings shown near the bottom of the furnace. Some experiments have been conducted with furnaces of this type using steam jets in some of the air inlets in order to obtain an agitation of the wood refuse dropping to the floor of the furnace. Results seem to indicate a slight improvement over natural draft. This boiler has been run at 200 per cent of rating continuously on wood refuse alone.

While we have been considering dry refuse only in this paper, Fig. 2 is given to indicate a successful furnace for wet hog fuel, such as would be available in a lumber mill. The fuel is introduced through the two openings in the top of the Dutch oven. The drop-nose arch aids materially in the combustion of this type of refuse by increasing the area of hot brickwork reflecting heat to the fuel bed, preventing stratification of the air and gases, and producing a high furnace temperature so essential for the proper combustion of wet refuse. Additional air is introduced through a hollow bridge wall to insure sufficient oxygen for burning the gases distilled from the fuel bed.

Fig. 3 shows what may be accomplished in the way of a special design to meet various limitations. The furnace was designed to burn both wet and dry refuse. On account of space limitations both as to length and height, the furnace volume is not all that might be desired. To overcome the deficiency in hot brickwork in the furnace, horizontal baffling was used. This not only increased the area of brickwork reflecting heat to the fuel bed, but also increased the length of gas travel. The suspended drop-nose arch accomplishes the same purpose as in Fig. 1. This furnace has met the requirements of smokelessness very satisfactorily. Ordinarily vertical baffling is preferred by the author in order to

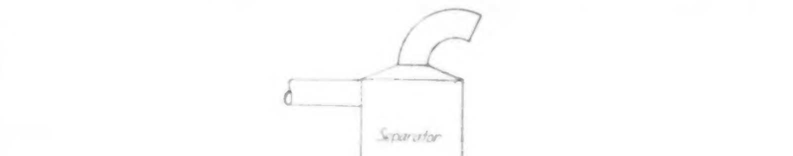

Fig. 6 Showing Means of Obtaining Uniform Feeding of Refuse

obtain a flow of the gases across the tubes and to prevent accumulations of ash on the horizontal surfaces, but in this case these advantages were offset by the desirability of obtaining the greater heat-reflecting surface and larger combustion space before the gases come in contact with the heating surface.

Fig. 4 shows a furnace somewhat similar to that in Fig. 1. The practice in the past has been to bring the furnace proper right up against the tube bank in vertical water-tube boilers. This resulted in the products of combustion coming in contact with the heating surface before combustion was sufficiently advanced. A large accumulation of ash around the bottom of the tubes and a dirty stack was the result. The setting shown in Fig. 4 very successfully overcomes the above disadvantages.

Fig. 5 shows a very successful setting for a horizontal-return tubular boiler. The auxiliary grate catches and burns a large amount of the fine shavings and sawdust that blow over the bridge wall. Air may be admitted below this grate and also through the hollow bridge wall above the grate.

Fig. 6 is given not so much to show a successful furnace as to indicate a means of obtaining uniform feeding of the refuse. In this case the refuse is the auxiliary fuel, coal being depended upon primarily. It will be noted that space limitations prevented designing a furnace of adequate proportions for successfully burning wood refuse.

The shavings, sawdust, and dry hogged cuttings are delivered from the separator to an overhead steel bin. From the bin the refuse flows by gravity to a screw conveyor, which in turn discharges through the top of furnace near the front. The speed of the conveyor, and consequently the rate of fuel feed, is under control of the fireman by means of a friction drive from a line shaft. Agitators are provided in the bin to prevent the material from "bridging." An air blast from a small fan is introduced into the discharge chute, as indicated, to prevent flarebacks and to obtain a better distribution of the refuse in the furnace. A runway passes over the tops of the furnaces, so a large chute and trap door are provided in each furnace for feeding rubbish and such wood refuse as cannot be put through the hog.

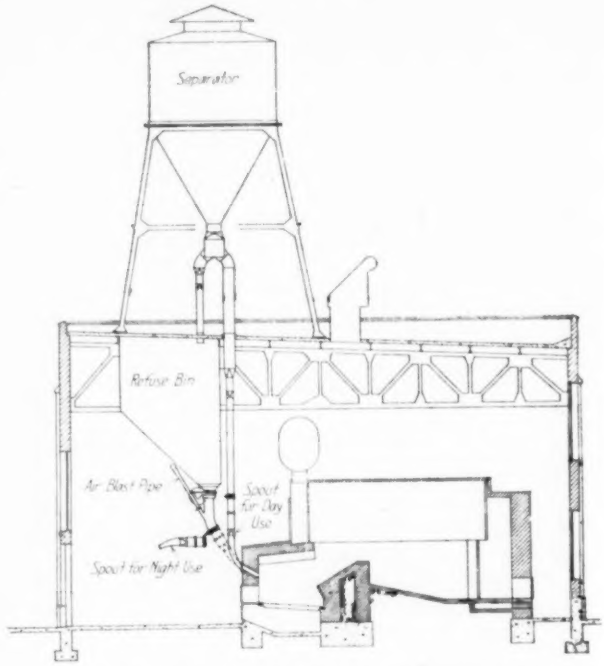

Fig. 8 Design of Moderate Cost for Small Plant

Fig. 7 shows a design which has worked out very successfully, both from the standpoint of the furnace and the method of feeding the coal and refuse. As will be noted, the furnace design is similar to that in Figs. 2, 4, and 5, using the drop-nose arch and auxiliary air inlet through the bridge wall.

The refuse is discharged from the separator into a large brick storage bin in the bottom of which is a double screw conveyor, the two screws turning in opposite directions and inwardly at the top. The screw conveyor conveys the refuse to a small exhaust fan, which in turn discharges to the secondary separator on the roof. From the sec-

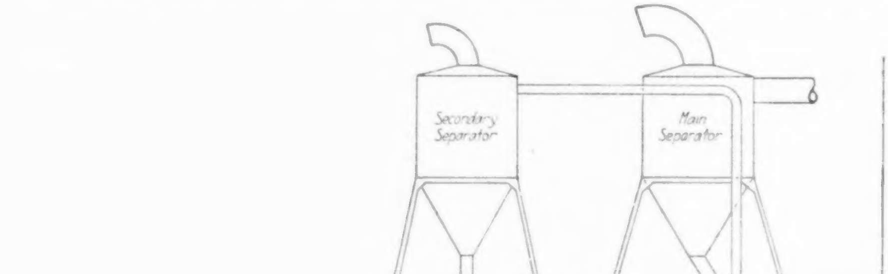

Fig. 7 Successful Design Both as Regards Furnace and Method of Feeding Coal and Refuse

ondary separator the refuse flows by gravity to the furnace in the usual manner. By means of a variable-speed motor the speed of the screw conveyor, and consequently the rate of flow of refuse to the furnace, is controlled in accordance with the load on the boiler.

As an auxiliary to the above a unit-type coal pulverizer and feeder is installed which is provided with automatic control so adjusted that if the supply of wood refuse is insufficient to carry the load the coal feeder will cut in automatically.

Fig. 8 indicates a furnace design and method of feeding used in a small plant where the expense of more elaborate equipment did not seem justified. In this case the shavings and sawdust are spouted direct to the furnace from the separator in the usual manner, the excess going to an overhead steel bin. Practically all cuttings are run through a hog and discharged to the same bin. When the manufacturing plant is not in operation the spout from the bin is inserted in the chute to the furnace and the contents of the bin discharged to the furnace by gravity, aided by the siphonic action of a jet of air from a fan. An agitator is installed in the bin to prevent bridging and to insure a fairly uniform rate of discharge.

This design is not offered as an ideal one, but it shows what may be accomplished at moderate expense. The refuse from this bin is fed to the furnace and consumed with far greater efficiency than would be obtained by feeding the material through the fire doors with a shovel.

The extended lip on the bridge wall induces a swirling action in the furnace which prevents stratification and insures a more intimate mingling of the air and gases. In this particular case this projecting lip had to be reduced somewhat from that shown, as it was found that too high a furnace temperature was obtained, resulting in high maintenance of the furnace walls and arch.

In conclusion, the author wishes to make an appeal for better engineering in the design and operation of woodworking plants. The woodworking industry has dropped far behind many other industries in the progress shown in plant design, manufacturing methods, etc. With the increasing keenness of competition it behooves every plant executive to scrutinize all departments of his plant with the greatest care. Today the saving of pennies in reducing costs may be as important as the saving of dollars was yesterday.

## Discussion[2]

Sern Madsen.[3] The paper is very complete in covering the subject of wood-refuse burning as conducted in the majority of woodworking plants, but it does not cover at all the apparatus or conditions of wood-refuse burning found in the larger and more efficient installations for burning of dry wood refuse.

The methods and apparatus described are those used in the average small mill burning dry wood refuse. Further than this, the installations described are designed and arranged for use of other fuel as make-up when wood refuse runs short.

Briefly, it describes the methods adaptable either to the small plant or to the larger plant where wood-refuse burning is a minor consideration.

The most efficient installation where wood refuse constitutes the major part of the fuel, or all of it, must be developed along radically different lines.

Reasons why the comparatively flat grates and "blow-in" system of feed are inefficient are:

1 The ratio of air to fuel entering above the grates varies as machines producing shavings vary.

2 The rate of fuel feed is not easily controlled to meet the demands for steam production.

3 The fuel burns like a bonfire, with cold air for maintaining combustion approaching the fuel from the top—the same side from which the heated gases resulting from combustion must leave. The highest temperatures cannot be obtained where the hot gases are extensively diluted with an excess of cold air.

4 The burning of the fuel is uneven. The air supply is not uniform to all parts of the fuel.

5 Building up of a cone or heap of shavings is ideal for generating gases for a subsequent explosion.

Other considerations that are essential for efficient wood-refuse burning are as follows:

1 The rate of fuel feed must be proportional to the demands for steam production and should preferably be automatically controlled.

2 The ratio of air for combustion and fuel feed should remain practically constant.

3 The fuel bed should entirely cover the grates and should be of nearly uniform depth. No holes in the fire should be permitted.

4 The air for combustion should enter primarily from below the grates so that the hot gases of combustion can leave uncooled from the top side of the fire.

5 Except in extremely high furnaces the theory of burning wood refuse in suspension is a myth. Therefore we must have grates.

To obtain the above conditions as nearly as possible, and to gain other advantages,

1 The air and fuel supply may be controlled by the steam pressure and maintained at a predetermined ratio.

2 Proper distribution of fuel on the grates can best be obtained by use of several gravity-feed chutes at or near the high end of a grate which slopes at from 30 to 40 deg. from the horizontal toward the back.

3 By keeping a well-distributed fuel bed of uniform depth, a moderate draft will supply a uniform air supply to all parts of the fuel.

4 A mechanical feed of shavings makes possible a storage of fuel when there is a surplus which may later be burned during a shortage.

5 All blocks and strips should be ground up in a hog and fired through the chutes like shavings.

6 Safety from backfiring or explosion is positively assured and does not depend on educating the fireman.

7 Smoke conditions are more easily controlled, but it should be remembered that burning of pitchy or knotty wood is not done most efficiently without some smoke.

8 Boiler-room labor and worry will be reduced by automatic apparatus.

As evidence that automatic gravity-feed wood-refuse burning is the most efficient, it might be stated that the largest of the sash and door plants along the Mississippi River have changed from the type of apparatus the author describes to the more modern types of feeding apparatus.

It might also be added that a change-over from the old apparatus at a Clinton, Iowa, plant saved during the first year's operation 2700 tons of coal on a 600-boiler-hp. installation.

In conclusion, let us decide first whether our furnace is to be designed for burning wood refuse as a major fuel or as a means of disposing of it along with other fuel. If the latter, then the author has described suitable apparatus, which, however, might be more efficient.

I. B. Whinery.[4] We had an experience with a small hori-

[2] Joint discussion of E. Winholt's paper on "Obtaining the Maximum Fuel Value From Wood Waste," and the preceding paper by Mr. Parks.

[3] Curtis Companies, Inc., Clinton, Iowa. Mem. A.S.M.E.

[4] Manager, Waddell Mfg. Co., Grand Rapids, Mich. Assoc-Mem. A.S.M.E.

zontal-return tubular boiler of about the size mentioned in Mr. Winholt's paper. We wanted to work out an economical way of keeping out this excess air, and devised a method which we think has possibilities. We located a slide in the down spout and operated it by a small motor-driven unit so that the slide would close off the opening for 50 seconds out of a minute and then open it up for 10 seconds. This allowed a charge of shavings to accumulate above the slide, which would drop into the furnace together with a gust of air, when the slide would close for another accumulation period. The idea was ultimately to provide it with a variable-speed mechanism so that when the shavings were coming faster the apparatus could be worked with a smaller accumulation period. One trouble was that the dust arched over in the spout from the slide, but it is believed that that can be overcome. We found that the device cut our coal consumption from 1000 lb. per day down to about 700 lb. per day, which shows it is possible to make a saving by keeping out excess air.

C. A. Crytser.[5] In designing the damper, Mr. Winholt had the control of air in mind as well as the safety feature. With this damper sufficiently weighted, it limits the amount of air to just about that necessary to carry the shavings into the furnace. For that reason he must supply his air at some other point. The air is supplied very largely through the damper, but the amount is controlled by hand and not automatically. Some sort of regulator might be devised, but it would have to operate on $CO_2$ content in order to take care of the situation. Mr. Winholt has found it possible to control the amount of air through hand operation, and obtain reasonable economy.

Mr. Parks showed on the screen two furnaces where there were large areas of floor. With powdered-fuel furnaces in Chicago, using tile on the floor has not been entirely satisfactory due to slagging which practically prevents heat transfer to the air.

Cast-iron plates, however, have been found to work perfectly. It is possible to blow the scale off them, and even with the high temperatures encountered in burning pulverized fuel there was never any trouble with burning of the plates.

As to squeezing moisture from the wet fuel in sugar mills with four to six hundred tons pressure on the rolls, it is impossible to get the moisture of the bagasse under 40 to 50 per cent.

R. K. Merrill.[6] We are operating 1700 b.hp. with four units, three of which are required during the factory operating period. All boilers are provided with screw feeds for shavings, which enter the boiler furnace through the furnace roof close to the furnace front. Two of the boilers are stoker-fired, using type E single-retort stokers made by the Combustion Engineering Company. The other two boilers are provided with plain herringbone grates, and the larger portion of the shavings is consumed in these two furnaces.

Originally, these last-mentioned furnaces were somewhat larger, but we found it necessary to install an air-cooled center wall between these two units which cut down the combustion space somewhat. The present furnaces are large enough to give us 1.66 cu. ft. of combustion space per b.hp. ahead of the first tube bank. We find that the air-cooled center wall saves considerable maintenance expense on the setting. Previous to the introduction of this center wall, we were considering an increase in the combustion space by dropping the grates down into the ashpit, which is rather deep, due to the fact that the boiler room has a basement underneath and ashes are removed at this point. We therefore agree with Mr. Parks that a maximum possible combustion space similar to installations for powdered-coal burning would be desirable.

The Ford Motor Company installed at the Lincoln plant a pair of return tubular boilers, which were originally obtained from some of the ships scrapped by the company, over a furnace which was in excess of 24 ft. high above the grates. This was for wood-refuse burning, and the writer is informed that the setting is very satisfactory. There is, of course, a limit to the size of wood-burning furnaces which is determined by the cost of these furnaces and beyond which point it would not be economical to go.

We find that the automatic control referred to by Mr. Parks is very handy for controlling the speed of the stoker engine which drives the shavings screws. It was a very simple matter to connect a wire from the valve on the engine to the hydraulic damper and turbine-control mechanism furnished with the type E stokers. This gives us a very close control of our steam pressure, which is not usual in wood-burning plants depending upon manual control of the draft and fuel.

We are using a crusher of the swinging-hammer type for reducing our blocks and cuttings to a size suitable for handling in the blow-pipe system. This has no knives requiring frequent sharpening, but the power consumption is rather high. We have found that a periodical tearing down and inspection of this machine every six weeks has paid well over a period of three years. Originally, the machine was set up and run until something happened, but the recurring frequency of these accidents, together with several fires, taught us the necessity for the above-mentioned practice. No material with nails or pieces of metal in it is fed through the machine. Incidentally, this machine now requires a motor which is twice the size of the one recommended by the maker.

C. A. Hamilton.[7] When I came to Grand Rapids and came in contact with the woodworking factories, I found that a $CO_2$ content of 4 to 6 per cent was a high average for the ordinary run of plant where they shoot shavings through the cyclones. In one plant with three boilers equipped with Dutch ovens, we installed screw feeders from a storage bin on each boiler, operated by a motor through a flexible drive with a 10 to 1 ratio. The flue-gas analysis on that installation was so low that I am ashamed of it. On the other hand, the performance seemed fairly good. The coal consumption went down, and in general the operation has been very satisfactory.

A screw feeder installed on a cyclone may produce a nuisance through the dust that carries over from the top. The city of Grand Rapids got after our company for such a nuisance, so we started out to eliminate that dust, which we did by piping from the cyclone into a bin where we sprayed the dust, and then enlarged the pipe area to a point where we reduced the velocity of the air down to about 3 ft. per sec.

R. K. Merrill.[6] Referring to Mr. Hamilton's remarks: With a portable $CO_2$ apparatus we have shown at least 13 per cent of $CO_2$ in our furnaces with plain grates, where the majority of our shavings are burned. Some hand-fired coal was also burned at the time of these tests.

C. A. Ross.[8] In the second table of Mr. Parks's paper it is stated that the available heat per pound of fuel with 70 per cent moisture is 17.7 B.t.u. That means a pound of fuel is 0.59 lb.

[5] Tower Construction Co., Chicago, Ill. Assoc-Mem. A.S.M.E.

[6] Industrial Mechanical Engineer, American Seating Co., Grand Rapids, Mich. Mem. A.S.M.E.

[7] Giffels, Hamilton & Wecher, Grand Rapids, Mich. Mem. A.S.M.E.

[8] Vice-President and Engineer, Piqua Handle & Mfg. Co., Piqua, Ohio. Assoc. A.S.M.E.

dry wood and 0.41 lb. of water. The removal of that water from the wood would take approximately 1000 B.t.u. per lb., or 420 B.t.u. for 0.41 lb. By removing it the fuel could be charged into one having 7000 B.t.u. per lb. The question arises whether any one has ever tried to dry wood refuse with heat from the stack before burning it, thus getting the additional heat indicated.

Kent says the heating value in B.t.u. per lb. dry is from 5400 to 6830. The heat at 70 per cent wet would be:

$$\left(\frac{100}{170}\times 6000\right)-\left[(212-50)\times 1+970+(600-212)\times 0.5\right]\frac{70}{170}$$
$= 2950$ B.t.u. (about)

Here

6000 = average B.t.u. per lb. of dry fuel above 50 deg. to 600 deg. fahr.
50 = initial temperature of fuel
970 = latent heat of contained water
0.5 = specific heat of steam
600 = final temperature of flue gases.

Theoretically there is only a saving of 194 B.t.u. by previous drying, and this will be lost in the drying, but the previous drying will bring about a higher furnace temperature.

B. M. Baxter.[9] I wish to emphasize the excellent point brought up by Mr. Parks, that the volume of furnace gases needs very careful consideration, especially where there is moisture in the fuel.

Some ten or twelve years ago I had occasion to look into the performance of certain boilers which were being fired with a material similar to spent bark in a tanning-extract plant in the South. This material ran very wet. The plant had been designed with vertical boilers much like those shown in this paper, except the tubes were small and the spaces were quite close. Fortunately, there was induced draft available, but one thing which was extremely puzzling was an excessive draft drop through those boilers.

A little thought in connection with the large amount of moisture contained in that fuel, which ran around 65 per cent, indicated that the volume of gases was far beyond the normal amount. That explained the high draft drop, which was corrected by a change in the baffling.

An interesting point in connection with the use of high-moisture-content fuels was the recovery of the heat from the stack gases. Naturally, with a large amount of moisture which must be evaporated and superheated, the stack losses are excessively high. In this instance, special economizers were designed.

Experience in another plant in that neighborhood indicated that the ordinary cast-iron tubes could not be used in the economizer because a deposit would stick to them and clog the scrapers. In fact, so much trouble developed with the cast-iron economizers that they were abandoned. In this case an economizer was developed using a steel-plate tank, through which ordinary boiler flues were thrust, expanded, and rolled in. This economizer proved quite successful and about 150 deg. rise was obtained in the feedwater. However, on account of the slow circulation of water in this economizer the tubes corroded and pitted quite rapidly.

It is quite common practice to discharge shavings from cyclones direct into the furnace. Considerable air is required to transport the shavings. The question arises how to adjust the amount of air necessary for the mechanical transport of the shavings to the amount properly needed for combustion.

Paul H. Bilhuber.[10] We have found it very satisfactory to combine coal and shavings in the same furnace and then discontinue the use of coal, reserving this furnace entirely for wood shavings, and have secured fairly good efficiency from it on that basis. I should like to ask whether Mr. Parks's furnace design is applicable to both shavings and pulverized coal, and whether an immediate change can be made from shavings to pulverized coal and the same efficiency be had from either of those fuels. Also whether it is possible to economically pulverize No. 1 buckwheat anthracite and whether that is less efficient to pulverize than bituminous coal or anthracite of the larger sizes.

B. M. Baxter.[9] The difficulty about spouting direct from the cyclone arises from the fact that the stock comes into the cyclone intermittently as it is freed through the machines in the plant. The blast in the cyclone is nearly constant at times, the fuel will come down in great volume, and again the spout will be empty. In considering this matter in the rearrangement of a plant ten or twelve years ago, the expedient mentioned by Mr. Parks, that is, a screw feeder, was adopted, which eliminated the difficulty. In my opinion it is the only proper way to feed.

C. W. Gordon.[11] I should like to ask a few questions. First, what commercial disposal is made of the wood ash? Second, what $CO_2$ is maintained in these furnaces? Third, what flue gas temperatures are obtained? Fourth, what boiler efficiencies are obtained with the various arrangements which have been shown on the screen? One type of furnace which has not been discussed consists of an airtight pressure chamber into which wet wood chips are fed by conveyor. Air at forced draft is introduced under the grates and a form of wood gas is therefore generated in this chamber. The gases pass through a small throat at high velocity and burn in a large combustion chamber under the boiler. These wood chips therefore burn with a $CO_2$ of from 13 to 15 per cent, and consequently the equipment operates with excellent results. We are interested in the problem mainly from the standpoint of superheater designs. The size of a superheater depends primarily on the amount of gases which pass over it. The $CO_2$ is a measure of the gas weight. Unless we are advised to the contrary it is our customary practice to assume a $CO_2$ of 8 per cent and this discussion indicates how far one can go wrong in a case of this kind.

W. T. Ritter.[12] I wish to second as well as emphasize Mr. Parks's remarks concerning the need of instruments in the average boiler plant, especially that of the woodworking establishment.

In my going from one plant to another, I find more unused $CO_2$ recorders, either automatic or hand operated, and draft gages so dirty that they could not be read if they were hooked up. Therefore it behooves us to think of the human element in the operation and maintenance of these instruments, and the employment of a higher type of operator who will use them more frequently than is now the practice.

I differ somewhat with Mr. Parks on the comparative value of wood and coal fuel. The heating values that he gives are about 2000 to 3000 B.t.u. higher than any authoritative ones I have seen. The average B.t.u. value of bone-dry wood will run somewhere between 7000 and 9900 B.t.u. On the same

[11] Mechanical Engineer, The Superheater Co., New York, N. Y.

[12] Burke Engineering Co., Holland, Mich. Jun. A.S.M.E.

basis, this figure for wood refuse should be compared with the B.t.u. value of 15,500 for bituminous coal, ash- and moisture-free.

As to the moisture content of the wood as found in most woodworking plants, Mr. Parks states that it is somewhere in the neighborhood of 5 per cent. Our experience in combustion work shows us that it is anywhere from 20 to 30 per cent. Wood refuse, even though it be kiln dried down to 5 per cent, will absorb quickly another 5 or 10 per cent the minute it is released from the bins.

As I see it, however, for every 3 lb. of wood we can expect to save about 1 lb. of coal instead of 2 to $2^1/_4$, as Mr. Parks states. I mention this because some woodworking manufacturers may be disappointed in their savings, and wonder why they are not higher.

There are places for powdered-coal installations in connection with burning of wood refuse and places for stoker installations. Two of the determining factors are:

1 The ratio of the amount of wood available or to be burned as compared with the amount of coal necessary to make up the full-load requirement.

2 The extent and intermittency of the wood supply. That is, how often the wood supply runs out and it is necessary to turn to coal.

Theoretically, powdered fuel would seem to be best for auxiliary or boosting in wood-burning or partial wood-burning furnaces. For the moderate-sized plant, up to 300–350 hp., stoker firing is the more economical when cost of operation, $CO_2$ performance, and efficiency are considered.

We manufacture a small Dutch-oven furnace, which we quite frequently install with so-called Scotch-type boilers, as well as tubular boilers. This furnace has just a little under $^3/_4$ cu. ft. volume per rated hp. Yet when connected up with a Scotch boiler, with about a $13^1/_2$-in. throat between the end of the rear grate and the heating surface of the boiler, we obtain absolutely smokeless results, and under normal operating conditions around rating obtain from 11 to 13 per cent of $CO_2$. The efficiency runs anywhere from 68 to 73 per cent. In a furnace which has a volume of less than $^3/_4$ cu. ft. per hp., these results are largely due to the swirling action caused by the wing walls built as a part of the bridge wall and by the cyclonic effect on gas travel produced by firing alternately opposite sides of the furnace. In the case of the furnace mentioned by the author, I do not believe that the high maintenance cost was due to the swirling action—it was really due to the radiating effect of the heat, which melted or burned away the brickwork.

L. H. Cutten.[13] Much has been said about the savings due to utilizing wood waste as fuel, but little about the cost of getting this wood fuel into the boiler. If the plant is small and the boiler house connected immediately with it, and a single cyclone can be used, it may be simple. The particular problem that we have is a wood shop 1000 ft. from the boiler house, with two or three tons of waste material a day, to be burned under a boiler using from 10 to 30 tons of coal a day. We have not been able to justify the expense to make the saving.

C. B. Norris.[14] What would be the minimum percentage of wood refuse that could be used in conjuction with coal to any advantage? We have possibly but 10 per cent to throw into our furnace. Perhaps there is a point where it would be better for us to burn our wood refuse in a bonfire, rather than disturb the coal in the fire with it.

### Mr. Winholt's Closure

The discussion on the paper which I presented has brought out a considerable number of theories regarding the burning of wood fuel, and of methods of burning it and of controlling fuel and air. It is conceded that automatic regulation on fuel as well as air is of a great advantage, but the boiler setting, the construction of the furnace, and other details are the most important items in the efficient burning of such fuel.

The paper as presented and the illustrations as shown refer specificially to certain applications. All of these installations are in operation and have been running for a number of years, and experience with these furnaces has indicated their suitability for the purpose. Theories of wood burning may be evolved afterward.

With the methods of furnishing fuel as well as air, which are discussed in the paper, it is absolutely necessary that the fuel be introduced with a certain velocity so that the heavy particles of wood will be delivered on the grate near the bridge wall, at which point they will form a pile which gradually spreads until it covers half or more of the grate. The other part of the grate is to be left uncovered for the admission of sufficient air to efficiently burn this fuel. Combustion takes place around the pile on the grate in the shape of a horseshoe. No air is allowed to come through the pile and burn, neither from the rear nor in the center. The air which enters with the shavings supports the surface combustion, and the fact that $CO_2$ up to and above 15 per cent is easily obtained and no combustible wood is deposited in the rear pass of the boiler is proof that combustion takes place very efficiently.

It is of course contrary to the theories and to the ordinary understanding that wood should be burned in a pile and with surface combustion, instead of being burned on grates with the air passing through them, similar to coal. However, the above method has been tested in the installations described in the paper and is working very satisfactorily.

It is of course necessary to see such an installation to fully grasp its significance. It must be conceded that a 344-hp. boiler with a total furnace volume of 455 cu. ft. and a grate surface of 28 sq. ft., supplied with wood shavings and generating up to 600 to 666 hp., must have some merit to it.

The boilers as described are arranged to dispose also of all factory refuse which is ordinarily swept up around the plant and which must be brought to the boiler room and fired by hand.

In conclusion, it should be stated that a prominent sash and door works located in the Tri-Cities is burning wood shavings exclusively in its power plant and operating an electrical load of approximately 1000 hp. in addition to heating the plant, and that this is being accomplished by burning wood shavings by means of a shavings system and a cyclone feed. The mill wood from this establishment is being sold, and no coal whatsoever is utilized in making steam under the boilers. This concern used approximately 20,000,000 board feet of lumber for its product in one calendar year, and the power plant produced all the heat, light, and power for it, or a total of slightly more than 2,000,000 kw-hr. It is doubtful whether this performance is paralleled in very many woodworking establishments.

### Mr. Parks's Closure

Replying to Mr. Ross, our experience has been that it costs just as much, if not more, to dry refuse outside of the furnace by some auxiliary use as it does in the furnace. In other words, it takes no more B.t.u. in one place than another.

In one industry in which we have done considerable work,

the tanning industry, the so-called "spent" bark from the leach where they make their tanning liquids, is delivered to the boiler house with a water content of about 65 per cent. We made some experiments at one plant by running this refuse, this spent tan bark, through what might be called a wringer, and attempted to press out part of the moisture. The experiment was successful in that it indicated that about 10 per cent of the moisture could be removed, but that is about all that can be extracted by auxiliary mechanical methods. While the experiment was fairly successful, the removal of that 10 per cent did not seem to justify expending the power required to run the wringer. So it was finally given up and the refuse spent bark was simply delivered to the furnace, carrying 65 per cent moisture. That meant, of course, that a lot of heat had to be spent in drying it, but at the same time there was a net value resulting that was quite considerable.

In regard to Mr. Baxter's comments, it is of course rather a difficult problem to control the air when spouting refuse shavings direct from the separator into the furnace. As Mr. Baxter says, there is a large amount of air required in order to mechanically transport the shavings. I know of no good way of controlling that air in accordance with the fuel where spouting direct from the separator.

Mr. Winholt, I believe, has accomplished considerable in that line by the use of that balanced damper which acts as a sort of obstruction in the path of the air, and forces more of it to be discharged through the regular vent on the separator.

Another experiment we conducted was at the plant of the Grand Rapids Store Equipment Company, where we used auxiliary feeding equipment, taking the refuse out of the bottom of the shaving bin and employing an auxiliary separator in order to reduce the amount of air. I do not know of any good way of controlling the air exactly in accordance with the fuel except by using something like a screw feeder direct from the furnace bin into the furnace, where the shavings are delivered into the furnace practically without any air, and the air is controlled either from above the grate or through an auxiliary air inlet, or by some similar means.

Referring to Mr. Bilhuber's discussion, I have never had much experience in pulverizing anthracite coal. We get very little of it in our district for plants. Pulverized bituminous coal, however, has given quite satisfactory results. Where the furnace volume is sufficiently large we have had quite satisfactory results and fairly high efficiency, both in using the refuse alone and the powdered coal alone in the same general type of furnace.

Replying to Mr. Gordon, in the majority of plants it has been impossible, unfortunately, for us to get the stack data because there are very few plants—in our neighborhood, at least—that are equipped with apparatus and instruments that enable one to make these tests. Naturally, while we should like to obtain the benefit from making these tests, we cannot go to the expense ourselves in all cases, and in many cases the owners are unwilling to make the outlay themselves.

In a wheel-manufacturing plant in Lansing, Mich., we got rather poor efficiencies and poor results so far as $CO_2$ was concerned. We were cramped for room and could not get the furnace volume we wanted.

In the larger furnace described in the paper with the closed type of boiler, using pulverized coal, we got an efficiency of about 72 per cent burning wood refuse, with a stack temperature of about 500 deg. fahr.; burning coal, the efficiency was about 76 per cent.

With reference to the question asked by Mr. Norris, in general, I should say with only 10 per cent of the fuel used being wood refuse, the determining factor in the furnace design would be largely the use of coal. At the same time it would seem that that furnace should be designed so that wood refuse could be used to advantage, for it would have a decided fuel value, and it would be better to burn it under the boiler than outdoors.
